Age-related changes in astrocytes, tanyocytes and the microvasculature were investigated in the median eminence (ME) of the anterior hypothalamo-hypophyseal system of 2- and 24-month old rats by means of immunocytochemistry and scanning electron microscopy. A computer-assisted image processing system showed a significant increase of the glial fibrillary acidic protein (GFAP) immunoreactivity in the internal layer (IL) and the perivascular region of the external layer (EL) of the ME with age. However, no remarkable changes in either layer could be detected employing vimentin immunoreactivity. An immunoelectron microscopic study revealed that the number of the GFAP-immunoreactive processes markedly increased with age in regions surrounding the capillaries of the EL. Therefore, it may be considered that, in both layers, the astrocytic cell bodies and associated glial processes exhibit a significant increase with age. Investigation of the microvasculature under a scanning electron microscope demonstrated the development and the sinusoidal progress of the external capillary plexus with age, but these changes were not observed in the internal capillary network of the ME. In conclusion, the results of the present study showed a close correlation between the increase of the GFAP-immunoreactive astrocytes and the development of the external capillary plexus. In addition, there was a close correlation between the increase in the GFAP-immunoreactive astrocytes and the sinusoidal progress.

Key words: immunocytochemistry, median eminence, astrocyte, microvasculature, rat

I. Introduction

Many different types of cellular components, such as nerve endings and glial processes, have been identified in the median eminence (ME) of the mammalian species [21]. It is thought that these glial cells are involved in the regulation of the release of the releasing/inhibiting (R/I) hormones in the ME [11, 13, 15–17, 26].

Tanyocytes and astrocytes have been identified in the ME [3, 4] by immunocytochemistry for vimentin (VIM) [19, 24] and glial fibrillary acidic protein (GFAP) [5, 22].

Tanyocytes are immunoreactive to both VIM and GFAP [24]. These cell bodies are located in the ependymal layer and send processes to the capillaries of the primary capillary plexus of the hypophyseal portal system [18] in the palisade layer and the perivascular region [7, 23]. Astrocytes are immunoreactive to GFAP and immunonegative to VIM [4]. Astrocytic cell bodies are mainly distributed in the subependymal layer and their processes have been observed throughout the ME [26].

In the ME, it has already been clarified morphologically that the GFAP-immunoreactive processes are in close contact with nerve endings such as the synapses, and a specific contact pattern is also exhibited between these processes and the basement membrane of the capillaries in the perivascular region [26]. The microvasculature of the ME in the anterior hypothalamo-hypophyseal system (HHS)
was investigated in the rat by Murakami et al. [18]. However, very few studies have focused on the age-related morphological changes in glial cells and the microvasculature in the ME.

Therefore, we employed immunocytochemistry for VIM and GFAP, and the plastic injection method [20] in order to investigate the age-related changes that occurred in glial cells and the microvasculature in the ME.

II. Materials and Methods

Experimental animals

Twenty-four young adult male Sprague-Dawley (SD) rats (2 months old, young adult group, body weight; about 270 g) and 20 aged male SD rats (24 months old, aged group, body weight; 870–980 g) were used in the present study. All rats were purchased from Charles River Japan, Inc. (Atsugi City) and housed in a temperature-controlled room (20°C). All rats were maintained in individual cages under a light/dark cycle (light on at 0700 and light off at 1900) and were given free access to food and water.

The Committee of Animal Research, Kyoto Prefectural University of Medicine, approved the experiments done in the present study. The present study was conducted according to Guidelines for Animal Research at Osaka Dental University and the National Institute of Health (NIH) Guideline for the Care and Use of Laboratory Animals.

Immunocytochemistry

Light microscopic immunocytochemistry

Ten animals in each group were perfused under deep pentobarbital anesthesia (40 mg/kg, i.p., Nembutal®) via the left cardiac ventricle with 0.1 M phosphate-buffered saline (PBS) and a fixative containing 4% paraformaldehyde and 0.2% picric acid, which was adjusted to pH 7.4 with 0.1 M phosphate buffer (PB). Then, the brain of each animal was immediately removed. Tissue blocks, including the ME, were dissected from the hypothalamus and then post-fixed in the same fixative for 24 hr at 4°C. After fixation, the tissue blocks were immersed in 20% sucrose in 0.1 M PB for 24 hr at 4°C.

Serial frontal free-floating sections (30 μm in thickness) of the young adult and the aged groups were cut with a cryostat and stored in 0.1 M PBS containing 0.1% Triton X-100 for 24 hr at 4°C. Then, the sections were processed for the avidin-biotin complex (ABC) method using antibodies against VIM and GFAP. The free-floating sections were incubated in the anti-VIM and the anti-GFAP sera (VIM, dilution 1:1000, Sigma; GFAP, dilution 1:1000, DAKO) in 0.1 M PBS containing 0.1% Triton-X 100 for 72 hr at 4°C. After the treatment, the sections were incubated in the secondary antibodies (VIM, biotinylated anti-mouse IgG; GFAP, biotinylated anti-rabbit IgG, Vector Lab. Inc.) overnight at 4°C and then were treated with the ABC solution (dilution 1:1000, Vector Lab. Inc.) overnight at 4°C. They were exposed for 10 min at room temperature to a 50 mM Tris-HCl buffer containing 0.01% 3,3′-diaminobenzidine 4HCl (DAB) and 0.005% H2O2. All specimens were marked to discriminate the individual animals, and all free-floating sections of the young adult and the aged groups were reacted in the same solution for the same amount of time. All sections were mounted on glass slides and examined under a light microscope.

The specificity of the anti-VIM and the anti-GFAP sera were confirmed by preabsorption with the respective antigens (1–100 mg), which completely abolished immunostaining.

Quantification of immunocytochemistry and statistical analysis

A computer-assisted image processing system was employed to investigate the quantitative analysis of VIM and GFAP immunoreactivity. The age-related changes in the expressions of VIM and GFAP in the ME were examined.

Ten serial frontal sections of the middle part of the ME were randomly selected for each animal and used to quantify the VIM and GFAP immunoreactivity in young adult and aged groups.

For expediency in the quantitative analysis, the ME was divided into sixteen blocks as shown in Figure 1. The optical density (OD) of the VIM and the GFAP immunoreactivity in each block was measured using NIH image software and the background OD was excluded from the ODs of each region. The OD values in 1, 4, 7, 10 and 13 blocks were summed up as those of the internal layer (IL), those in 2, 5, 8, 11 and 14 as the middle layer (ML) and those in 3, 6, 9, 12 and 15 as the external layer (EL). Furthermore, the values for individual layers were added up and defined as those of the total layer (TL).

The sections were digitized as gray-level images on a computer-assisted image processing system. Each pixel was quantified as 1 of 256 gray levels. A gray-level value of zero
they were fixed in a fixative without glutaraldehyde for 24 hr. For electron microscopic immunocytochemistry, the sections were additionally fixed in 1% OsO₄ solution after the decalcification as mentioned above. Two of these animals were prepared as specimens for the observation of the artery of the blood supply to the ME, and the other two animals as specimens for the observation of the capillary plexus from the dorsal side.

Each specimen was placed on a sample carrier with conduction tape and conduction paste (DOTITE®). Five decalcified heads from each group were cut sagitally to the vicinity of the median plane of the ME with a microtome under freezing conditions. The specimens were digested in the 5% sodium hypochlorite solution and a 10% sodium hydroxide solution, and then prepared for the microvascular corrosion cast of the pituitary system observed from the median plane.

In order to examine the arteries of the blood supply and the microvasculature of the whole ME in three dimension, the soft tissue of four of the nine young adult rats was digested in the same solution after the decalcification as mentioned above. Two of these animals were prepared as specimens for the observation of the artery of the blood supply to the ME, and the other two animals as specimens for the observation of the capillary plexus from the dorsal side.

Each specimen was placed on a sample carrier with conduction tape and conduction paste (DOTITE®), coated with gold with an ion-coater (JFC-1500, JEOL) and examined under a scanning electron microscope (SEM) (JSM-5500, JEOL; working distance, 48 mm; acceleration voltage, 5–15 kV).

III. Results

Light microscopic immunocytochemistry

VIM-immunoreactive tanycytic cell bodies were located in the ependymal layer of the IL, just below the third ventricle. Tanycytic processes were observed to extend radially toward the floor of the brain and around the capillaries in the EL. In the mediobasal hypothalamus, except for the ME regions, tanycytic processes were found running more horizontally (Fig. 2a). In a comparison of the young adult and the aged groups, no prominent morphological differences were observed. The distributions of these tanycytic processes were similar for the two groups in spite of the age-related changes in the size of the ME (Fig. 2b).

However, the distribution of the GFAP in the ME was greatly different from that of the VIM. The GFAP-immunoreactive tanycytic cell bodies were located in the ependymal layer of the IL, and the GFAP-immunoreactive processes ran toward the EL. The GFAP-immunoreactive astrocytic cell bodies were also found in the subependymal layer just below the ependymal layer, and the GFAP-immunoreactive processes ran toward the EL (Fig. 2c). The expression of the GFAP in the ME of the aged group showed a remarkable increase in comparison with the young adult group. Especially, many astrocytes and their processes were observed to extend from the subependymal layer in the IL to the perivascular regions in the EL (Fig. 2d).
Quantitative analysis of the VIM and the GFAP immunoreactivity in the ME

In a comparison of the young adult and the aged groups, no significant differences in the VIM-immunoreactive density in the tanycytes were found in any of the layers (young adult group IL, 213.16±7.60; ML, 182.14±2.47; EL, 192.49±3.47, aged group IL, 214.29±13.60; ML, 182.60±14.28; EL, 193.54±12.31). Additionally, no significant differences were detected in the ODs of the TL in the ME (TL young adult group, 195.93±4.41; aged group, 196.81±13.08) (Fig. 3a).

In contrast, the GFAP immunoreactivity showed significant differences in both groups (Fig. 3b). In both the IL and the EL, the GFAP immunoreactivity was significantly higher in the aged group than in the young adult group (young adult group IL, 190.24±4.35; EL, 160.07±5.88; aged group IL, 211.51±5.25; EL, 196.46±9.38). Especially, a remarkable increase in GFAP immunoreactivity was observed in the EL. However, no significant differences were detected in the ODs of all layers, the GFAP immunoreactivity showed significant age-related changes (TL young adult group, 179.53±5.16; aged group, 202.66±6.62) (Fig. 3b).

Immunoelectron microscopy

Immunoelectron microscopic findings for the young adult group were previously reported by Tamada et al. [26]. In the aged group, astrocytic cell bodies were observed abundantly, not only in the subependymal layer, but also in the reticular layer of the ML. Especially, cell bodies showing a strong GFAP immunoreactivity were identified in the vicinity of the capillary invading the reticular layer (Fig. 4a). Moreover, the GFAP-immunoreactive processes were distributed around the abundant capillary of the hypophyseal portal system in the perivascular region. In the aged group, these processes showed a tendency to increase, in comparison with the young adult group. In addition, the size of the area in which these processes were detected around the capillary remarkably increased with age (Fig. 4b).

Microvasculature investigation employing SEM to determine blood supply to the ME in the young adult group

The microvasculature of the ME was observed on the ventral side of the third ventricle (Figs. 5, 6a). The microvasculature of the adenohypophysis was observed behind the microvasculature of the ME (Fig. 5). The hypophyseal portal vessel, consisting of about ten venules, was observed connecting with both of the microvasculatures (Fig. 5). Functioning as blood supply to the ME, the anterior and
the middle hypophyseal arteries arising from the internal carotid artery were also observed (Fig. 5). From the lateral-ventral view, the accessory middle hypophyseal artery could not be observed, because this artery was located dorsal to the microvasculature of the adenohypophysis (Fig. 5).

Microvasculature in the ME of the young adult group and the aged group

Young adult group

The microvasculature of the ME consisted of the external capillary plexus and the internal capillary network (Fig. 6a).

External capillary plexus

The external capillary plexus was located in the EL and the ML (Fig. 7a). The middle part of the ME was the thickest in the dorso-ventral height (about 150 μm) (Fig. 7a). This plexus was composed of a capillary bed and capillary loops, and both were distinguished clearly (Figs. 6b, 7a).

The capillary bed, composed of many sinusoidal capillaries (6–20 μm in diameter), was congregated (Figs. 6b, 7a). It was located in the EL (Fig. 7a) and in close contact with the dorsal side of the hypophyseal portal vessels, which ran beneath the ventral surface of the ME (Fig. 7a).

Capillary loops projected to the dorsal side of the capillary bed (Figs. 6b, 7a). In addition, capillary loops were distinguished into simple low capillary loops (LCLs) in the EL.

Fig. 3. Quantitative analysis of VIM and GFAP immunoreactivity.

a: In a comparison of the young adult and the aged groups, no significant differences were demonstrated in VIM immunoreactivity detected in IL, ML, EL and TL. b: A significant increase was observed in GFAP immunoreactivity in IL, EL and TL of the aged group, in comparison with that of the young adult group (n=10, *p<0.001, **p<0.05). Error bars indicate the standard deviation of the mean.

Fig. 4. Electron microscopic immunocytochemistry for GFAP in the aged group. a: GFAP-immunoreactive astrocytic cell bodies were observed in the vicinity of the capillary in the reticular layer of ML. Many GFAP-immunoreactive processes (arrows) were identified around the capillary. b: There was a wide spread of astrocytic processes (arrowheads) ending around the capillary in the perivascular region of EL. N, nuclei of astrocytic cell bodies.
Ike et al.

and the ML (Figs. 6b, 7a) and complicated high capillary loops (HCLs) in the ML (Figs. 6b, 7a). The LCLs (46 μm in height) were simple hairpin loops, which were composed of one or two short ascending crura (6–11 μm in diameter) and one short descending crus (6–16 μm in diameter) (Figs. 6b, 7a). The HCLs (85–100 μm in height) showed a characteristic columnar or pyramidal shape when viewed as a whole (Figs. 6b, 7a). The tips of the HCLs bulged in a spherical or hemispherical form (Figs. 6b, 7a). The HCLs consisted of 2 to 4 ascending crura (5–14 μm in diameter) and descending crura (7–14 μm in diameter) (Figs. 6b, 7a).

**Internal capillary network**

The internal capillary network was located in the IL of the ME (Fig. 7a), and a small number of sinusoidal capillaries ran on horizontally, meandering on the dorsal side of the external capillary plexus (Fig. 6a, b). The network consisted of only two or three meshes of anastomotic capillaries (Fig. 6a, b). These sinusoidal capillaries were both thick (20–30 μm in diameter) and thin (10–12 μm in diameter), and were more the thick capillaries than the thin (Fig. 6a, b). The capillaries of the internal capillary network communicated with those of the capillary bed or the HCLs of the external capillary plexus (Figs. 6b, 7a).

**Hypophyseal portal vessels**

The hypophyseal portal vessels were venules (about 43 μm in diameter) running rostro-caudally, and were located on the ventral side of the ME (Fig. 7a, c). These portal vessels communicated with the capillaries of the capillary bed of the external capillary plexus (Fig. 7a).

**Aged group**

The external capillary plexus and the internal capillary network were observed in the aged group (Fig. 7b) as well as in the young adult group (Figs. 6a, 6b, 7a). Prominent morphological changes were observed in the external capillary plexus (Fig. 7b).

**External capillary plexus**

The external capillary plexus was located in the EL and the ML of the ME (Fig. 7b). The middle part of the ME was the thickest in dorso-ventral thickness (about 230 μm), and was enlarged about 1.5 times (Fig. 7b) in comparison with...
that (about 150 μm) of the young adult group (Fig. 7a). The external capillary plexus between the capillary bed and the capillary loops was distinguished clearly (Fig. 7b).

It was observed that the capillary bed developed dorsally in comparison with that of the young adult group (Fig. 7a), and was widely distributed from the EL to the ML in the ME. This bed was composed of sinusoidal capillaries (6–30 μm in diameter) (Fig. 7b).

Capillary loops were located in the IL on the dorsal side of the developed capillary bed (Fig. 7b). These loops were only low loops (22–32 μm in height) composed of two ascending crura (7–14 μm in diameter) and a descending crus (about 9 μm in diameter), and were not columnar or pyramidal HCLs (Fig. 7b), as was observed in the young adult group (Fig. 7a).

Internal capillary network

The internal capillary network was located in the IL and consisted of two or three meshes of anastomotic capillaries (Fig. 7b). This was observed as well as in the young
adult group (Fig. 7a).

The sinusoidal capillaries composing this network were 19–30 μm and 10–14 μm in diameter, which was not widely different (Fig. 7b) from those of the young adult group (Fig. 7a). However, these capillaries ran closely along the dorsal surface of the external capillary plexus (Fig. 7b).

Hypophyseal portal vessels

The hypophyseal portal vessels were about 88 μm in diameter, and were enlarged about twice in size (Fig. 7d), compared with that of the young adult group (Fig. 7c).

IV. Discussion

Experimental procedures in the present study

The ME was expediently divided into sixteen blocks for quantitative analysis of the GFAP and the VIM immunoreactivity. This division method was employed in order to examine the relationship between the age-related changes in immunoreactivity and the microvasculature in the IL, ML and EL. In this division method, the ependymal and the subependymal layers corresponded to the IL, the fibrous and the reticular layers to the ML, and the palisade layer and the perivascular region to the EL. After the measurement of OD in each block, the density was examined in contrast with the microvasculature in each layer.

To minimize the technical variations of the age-related changes of the GFAP- and the VIM-immunoreactivity in the quantitative analysis using a computer-assisted image processing system, all the free-floating sections of the young adult and the aged groups were marked and processed simultaneously in the same reactive solution for the same amount of time.

Age-related changes in glial cells in the ME

It was clarified that there was an age-related increase in the number of astrocytes [14]. There were also age-related hypertrophic changes in the astrocytes [1, 2, 25]. Zoli et al. suggested that these changes were one of the age-related phenomena in the hypothalamus [28]. However, very few studies have focused on the aged-related changes in glial cells in the ME. The quantitative analysis showed a significant age-related increase in GFAP immunoreactivity in the IL and the EL, but no age-related changes in the VIM immunoreactivity. Our quantitative data on the GFAP immunoreactivity suggested an age-related increase in astrocytes in the IL and the EL of the ME.

In contrast, experimental brain injuries produced the following results: (1) an increase of GFAP and an induction of its mRNA [8, 27], however, no proliferation of astrocytes was observed [10], (2) astrocytes produced several kinds of neurotrophic factors, such as nerve growth factor (NGF) [6, 9, 12]. These studies suggested that the number of astrocytes did not increase, but that the expression of GFAP and NGF increased in the astrocytic cell bodies with aging and injury. Additionally, these studies suggested that GFAP and NGF played important roles in supporting neuronal survival.

Moreover, in an in vitro study using the co-culture systems of glial cells and neurons in the ME, it was revealed that aged glial cells had the capacity to support neurite outgrowth and the survival of neurons [4]. Based on this experimental evidence, the age-related increase in GFAP in astrocytes of the ME was considered to contribute greatly to neuronal survival.

Age-related changes in microvasculature in the ME

Murakami et al. investigated the microvasculature of the rat HHS according to animal body weight [18]. Their research work, however, makes no mention with regard to the age of animals. In the present study, we clarified both the age (24 month-old) and body weights (870–980 g) of the experimental animals, and investigated the morphological changes in the microvasculature in the ME of aged rats with heavy weight body as compared with those used by Murakami et al.

Murakami et al. divided the microvasculature of the ME and the infundibular stalk in the HHS into the subependymal capillary network and the capillary bed. In the present study, we investigated only the microvasculature of the ME, and did not investigate the infundibular stalk. We regarded the subependymal capillary network as the internal capillary network, and the capillary bed as the external capillary plexus. In addition, Murakami et al. included the capillary loops in the capillary bed, while we divided the external capillary plexus into the capillary bed and the capillary loops. The reason why we employed this division was on the basis of the following evidence: Murakami et al. reported age-related changes in the capillary loops of the capillary bed, while we identified age-related changes in both the capillary bed and the capillary loops of the external capillary plexus. Therefore, we discussed age-related changes in the internal capillary network and the external capillary plexus in order.

The internal capillary network was located in the IL of both groups and it was an incomplete capillary network composed of only two or three meshes of anastomotic capillaries. In regard to the subependymal capillary network, Murakami et al. mentioned only that it was composed of anastomotic capillaries, and there was no mention of age-related changes in this network. In the present study, no age-related changes in the capillaries of this network were observed.

However, we found that the external capillary plexus developed with age according to the following positional changes. With advanced age, the capillary bed developed from the EL in the young adult group to the EL and the ML in the aged group, and as this development took place, a change was found from the LCLs and the columnar HCLs in the young adult group to the low loops in the aged group. Subsequently, both capillary loops became the low loops.

Moreover, with advanced age, the capillaries became thicker. In the aged group, the diameter of the capillaries in the EL were from 20 μm to 30 μm thicker than that in the young adult group, therefore, it was thought that sinusoidal
changes in the capillaries had advanced. Additionally, in the aged group, the external capillary plexus grew to a height about 1.5 times that seen in the young adult group. The diameter of the hypophyseal portal vessel became thicker in order to receive the increased blood flow from the external capillary plexus. From these facts, it was conjectured that the age-related changes in the external capillary plexus influences the age-related changes in the microvasculature of the hypophyseal portal vessels.

Relation between astrocyte and microvasculature in advanced age

In the IL, we clarified an age-related increase in the OD in GFAP immunoreactivity. It was suggested that the number and the enlargement of astrocytic cell bodies occurred in the subependymal layer with age [2]. As no changes were observed in the internal capillary network of the IL in either group, it was therefore thought that there was no correlation between the increase in the number of astrocytic cell bodies and the capillary network. However, it was conjectured that the number of astrocytes increased in the IL in order to receive the blood supply from the low loops of the external capillary plexus in the IL in the aged group.

In the ML, no significant increase in GFAP immunoreactivity was detected between the two groups. We clarified the age-related appearance of astrocytic cell bodies in the reticular layer of the ML in an electron microscope study. However, the number of astrocytic cell bodies that appeared in the ML of the aged group was very few, and so we concluded that they did not reflect the increase in OD in GFAP immunoreactivity. Additionally, it was also conjectured that the external capillary plexus developed into the ML in order to enhance the blood supply with these astrocytic cell bodies.

In the EL, it was shown that the age-related increase in GFAP immunoreactivity was due to the increased number of the GFAP-immunoreactive processes surrounding the capillaries. Furthermore, it was considered that the sinusoid of the capillaries progressed according to the increased number of these astrocytic processes with age.

In conclusion, the results of this study showed a close correlation between the increase of the GFAP-immunoreactive astrocytes and the development of the external capillary plexus. There was also a close correlation between the increase in the GFAP-immunoreactive astrocytes and the sinusoidal progress.

It is of importance to further elucidate what morphological and structural changes occur in the microvasculature in the ME after the dynamic changes of the astrocyte, and nerve processes and endings which may be induced by neuroactive substances such as R/I hormones, catecholamines and so on.
