Abstract

Type 2 diabetes mellitus is a serious metabolic disorder in the world. Oxidative stress, as a key role on the pathogenesis of diabetes, also results in the oxidation of phospholipids. However, studies on phospholipid oxidation in diabetes, especially directly focusing on oxidized and degraded phospholipid species, are quite limited. In this study, phospholipid profiles of diabetic zebrafish plasma were characterized by LC-HRMS and MS/MS, and the total amounts of each lipid class were compared. Furthermore, the key molecular species as biomarkers in distinguishing control and diabetic samples were investigated by orthogonal partial least squares discriminant analysis. Among the identified 114 phospholipid species in total, there were 11 hydroperoxides, 7 aldehydes, and 19 lysophospholipids found significantly elevated along with the increasing blood glucose, which were known as oxidation or degradation products. Furthermore, lysophosphatidylcholine 20:5 and lysophosphatidylcholine 22:6 were assessed as potential biomarkers in diabetic zebrafish. The current work would not only help to gain further insights into diabetes, but also contribute to find new clinical parameters for the screening of the promising antioxidant agents for its therapies.

Keywords Lipid oxidation, oxidized phospholipids, oxidative stress biomarkers, type 2 diabetes mellitus, zebrafish; LC-MS
Introduction

Diabetes mellitus, as a prevalent metabolic disorder, is characterized by hyperglycemia due to the inability to secrete insulin or use it ineffectively. Among all of the diabetes cases, more than 90% are type 2 diabetes mellitus. It is known that oxidative stress plays a key role in the pathogenesis of diabetes. Hyperglycemia stimulates several biochemical pathways that produce reactive oxygen species (ROS), such as oxidative phosphorylation, glucose autoxidation, advanced glycation end products (AGE) formation, and glucosamine pathway. Oxidative stress, in turn, leads to promote insulin disturbance, contributing to diabetes development. For example, it is known that ROS can damage mitochondria and significantly attenuate insulin secretion. Moreover, oxidative stress alters Ca\(^{2+}\) homeostasis to cause an increase in Ca\(^{2+}\) influx and triggers the activation of phospholipase to produce arachidonic acid. Furthermore, the prostaglandins derived from arachidonic acid are considered to be predominantly proinflammatory, which is the risky factor of oxidative stress.

Since the oxidative stress in diabetes disrupts the balance between free radicals and the antioxidant defense system of the cells, the relationship between lipid oxidation and diabetic complication draws researchers’ attention. Studies have been reported that diabetic complication is associated with elevation of the lipid peroxidation products, such as comparative studies on thiobarbituric acid reactive substances (TBARS), malondialdehydes (MDA), and isoprostanes (IsoPs) in diabetic individuals. Those compounds serve as the products of lipid peroxidation process. A better way to
investigate lipid peroxidation would be to directly analyze the original product, lipid hydroperoxides (L-OOH), rather than its secondary products. However, investigations directly targeted on the oxidized lipid molecules are quite limited.

Thanks to the development of mass spectrometry (MS) technologies, especially coupling it to high performance liquid chromatography (LC-MS) and tandem MS (MS/MS) in the recent years, researchers can successfully determine various of analytes in different samples. For the oxidized phospholipids, there have been reports on determination of different kinds of oxidized phospholipids in various of biological samples, including hydroperoxides of phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylycerine (PS), and cardiolipin (CL), as well as PC aldehydes (PC-CHO). Nevertheless, with regard to lipidomics in diabetes, although there have been studies on lipidomics via LC-MS, there are seldom reports on the changes of these oxidized phospholipids. In our laboratory, previous studies on various of lipid hydroperoxides (e.g. PC-OOH, TG-OOH, CE-OOH, CL-OOH) in different biological samples (e.g. blood, cell, lipoprotein) have been carried out. The investigated hydroperoxides were known as biomarkers for the oxidation degree of the sample matrix, and their LC-MS data could be the basis of further studies. Therefore, whether oxidized lipids could be considered as biomarkers for type 2 diabetes mellitus is of our great interest. The found of reliable biomarkers will not only help to clinical diagnosis, but also promote elucidating the mechanism of type 2 diabetes mellitus, and in addition contribute to screening the
potential agents for diabetic therapies. There is one report on the positive association between serum PC-OOH levels and blood glucose control in type 2 diabetes patients by Nagashima et al., yet there are more phospholipid oxidation products that to be clarified. An appropriate animal model is important to the in-depth studies on diabetes and anti-diabetic drug development. Most of the available models are rodent-based, which is labor-intensive, and because of ethical issues, only small groups of animals can be used. Due to the highly similarity to mammals in organ physiology and metabolism along with the less labor intensity, zebrafish (Danio rerio) has been considered as favorable animal to explore diabetes and its related diseases, being a favorable alternative to rodent. Recently Zang et al. developed a novel zebrafish model for type 2 diabetes mellitus, which was considered a promising platform for mechanic and therapeutic studies of diet-induced glucose intolerance and insulin resistance. In the present work, the omics analysis for phospholipids and oxidized phospholipids was performed to investigate the characteristics in the plasma from diabetic zebrafish. With the help of HPLC coupled to high resolution MS (HRMS) combined with multivariate statistical analysis, the levels of specific lipid molecules were semi-quantitatively compared, and the potential biomarkers for diabetic diagnosis were found.
Experimental

Chemicals

LC-MS grade chloroform, isopropanol, methanol, acetonitrile and water were purchased from Wako Pure Chemical (Osaka, Japan). Ammonium acetate and butylated hydroxytoluene (BHT) were obtained from Sigma-Aldrich (St. Louis, MO).

Other chemicals and reagents were of analytical grade and purchased from Kanto Chemical Industry (Tokyo, Japan) unless specified.

Plasma sample of the type 2 diabetic zebrafish

All animal procedures were approved by the Ethics Committee of Mie University, and performed according to the Japanese animal welfare regulation “Act on Welfare and Management of Animals” (Ministry of Environment of Japan) and complied with international guidelines.

The type 2 diabetes mellitus model zebrafish were prepared as reported previously. Briefly, male healthy zebrafish of AB and Tg(−1.0ins:EGFP)sc1 strain (the Zebrafish International Research Centre, Eugene, OR, USA) were maintained in Graduate School of Regional Innovation Studies, Mie University according to established protocols before modeling. The zebrafish were divided to control group (Con) and overfed group, both of which were fed with the commercial fish food Otohime B2 (Marubeni Nisshin Feed, Tokyo, Japan). The zebrafish in overfed group were conducted using an automated feeding system (Marukan, Osaka, Japan) for modeling. The fasting blood glucose level varied among the overfed zebrafish due to individual differences.
differences. Based on their fasting blood glucose, the overfed zebrafish were grouped into the medium blood glucose group (MBG, with fasting blood glucose less than 60 mg/dL) and high blood glucose group (HBG, with fasting blood glucose more than 60 mg/dL), as previously reported.\textsuperscript{25} In order to compare the influence of overfed period, two groups of were investigated: 1 month for short-term, and 7 months for long-term. For the 1-month experiment, $n = 10$ (Con), 7 (MBG), and 11 (HBG), respectively, and for the 7-month experiment, $n = 10$ for each group. The detailed blood glucose data was shown in Supporting Information Figure S1.

After fed or overfed for 1 month and 7 months, respectively, all the zebrafish were fasted overnight prior to anesthetization by 2-phenoxyethanol (500 ppm). Then blood collection was performed by heparinized needle, and their blood glucose level were determined by the handheld glucometer.\textsuperscript{27} Due to the blood volume limitation, for plasma lipid profiling analysis, blood from the same group was combined and pooled in micro centrifuge tubes. Then the pooled blood samples were centrifuged under 3,000 rpm at 4 °C for 10 min, and the plasma were obtained (approximately 60 $\mu$L). All the plasma samples were stored in −80 °C until use.

Total lipids extraction

The extraction procedure was according to Bligh and Dyer.\textsuperscript{28} In Brief, 20 $\mu$L of zebrafish plasma sample was extracted with 160 $\mu$L of cold chloroform/methanol 1:1 ($v/v$, with 0.002% BHT) twice, followed by combination of extract and dryness under vacuum. Then, the dried lipids were dissolved in 150 $\mu$L of methanol, centrifuged at
15,000 rpm at 4 °C for 15 min to remove any insoluble material, and thereafter stored at −80 °C until analysis. All the sample pretreatment was finished within 1 hour to avoid lipid degradation and auto-oxidation. All of the lipid extracts were prepared in triplicate.

**LC-MS conditions**

Lipid extracts were separated on an Atlantic T3 C18 column (2.1 × 150 mm, 3 μm, Waters, Milford, MA) connected to a Shimadzu Prominence HPLC system (Shimadzu Corp., Kyoto, Japan). A flow rate of 200 μL/min was used for the analysis, and the column and sample tray were held at 40 and 4 °C, respectively. MS analysis were carried out using an LTQ Orbitrap mass spectrometer (Thermo-Fisher Scientific Inc., San Jose, CA). The MS capillary voltage was set at 3.0 kV, the sheath gas (nitrogen) flow was set to 50 units, and the auxiliary gas (nitrogen) was set to 5 units. The MS\(^1\) data was obtained in Fourier Transform mode with resolving power 60,000 and a 2 Hz scan speed, while the tandem MS data was acquired using collision-induced dissociation in ion-trap mode and data-dependent acquisition, which included scans on the most intense ions in MS\(^2\) (collision energy of 35 V) and MS\(^3\) (collision energy of 45 V), respectively. These conditions were held constant for both positive and negative ionization mode acquisitions.

In positive mode, LC gradient elution was performed with a mobile phase of (A) 5 mM aqueous ammonium acetate, (B) isopropanol, and (C) methanol. The following gradient system was utilized: 0–1 min 4% A, 6% B, and 90% C; 1–10 min 2% A,
83% B, 15% C, and this ratio was kept to 19 min; 19–20 min returned to initial ratio for re-equilibration. The MS$^1$ scan range was $m/z$ 150–1100. In negative mode, the LC mobile phase was changed to (A) methanol/acetonitrile/water 1:1:3 (v/v/v, with 5 mM ammonium acetate), (B) isopropanol, and (C) methanol/acetonitrile 1:1 (v/v, with 5 mM ammonium acetate). The gradient program was as follows: 0–2 min 90% A, 0% B, and 10% C; 2–22 min 3% A, 82% B, 15% C, and this ratio was kept to 27 min; 27.01–30 min returned to initial ratio for re-equilibration. The MS$^1$ scan range was $m/z$ 250–1000.

Data analysis

The extracted ion chromatograms (EICs) were drawn within the mass tolerance of 5.0 ppm by Xcalibur 2.2 (Thermo-Fisher Scientific Inc.). The LC-MS identification of lipid molecules were executed with the help of LipidBlast $^{29}$ as well as in-house library.$^{18,30}$ The alignment, peak extraction, and EIC peak area integration from the raw data were utilized by the MS-label free differential analysis software package SIEVE 2.0 (Thermo-Fisher Scientific Inc.), of which the main parameters were set as follows: frames, 10 K; $m/z$ window, 0.01 Da; retention time window, 1.00 min; intensity threshold, 10,000. The exported EIC peak area data were treated as the intensities of analytes and used for further statistical analysis. The hierarchical cluster analysis (HCA) was performed using JMP 10.0 (SAS Institute Inc., Cary, NC), in which the Euclidean distance was used as a dissimilarity, and Ward’s minimum variance was used as a linkage rule.$^{31}$ And the orthogonal projection to latent structures discriminant
analysis (OPLS-DA) was processed using R software and the muma package, in which the S-plot was generated after Pareto scaling and mean-centering.

### Results and Discussion

**Phospholipid profiles of zebrafish plasma**

The representative LC-MS total ion chromatogram (TIC) of the zebrafish plasma lipid under positive and negative modes are shown in Figure 1A and 1B, respectively. A total of 114 phospholipid species, including the choline type of 29 PC, 6 PC-OOH, 7 PC-CHO, 8 lysoPC, the ethanolamine type of 15 PE, 5 PE-OOH, 5 lysoPE, the inositol type of 25 PI, 6 lysoPI, and the serine type of 7 PS and 1 lysoPS were detected and identified based on their retention behavior on a reversed phase column as well as the protonated/deprotonated ion peaks on HRMS. The LC-MS data were shown in Supporting Information Table S1.

In order to search significant variables in large dynamic range and avoiding noisy data efficiently, we performed normalization and centralization of EIC peak area of all the detected phospholipids using R software, followed by generating the heat map by JMP. Specific patterns of correlation between groups and phospholipid variables are visualized in Figure 2. The HCA dendrogram expressed different distribution pattern of each phospholipid species, and the red squares indicated relative higher contents in each row. Despite of exception, the variables of higher abundance in overfed groups (MBG and HBG of both 1-month and 7-month) mainly consisted of phospholipid...
hydroperoxides, aldehydes, and lysophospholipids, which suggested their elevated levels might be related to increased blood glucose levels. Some reports have suggested that lipid species containing less carbon atoms and less double bonds are associated with an increased risk of diabetes or other metabolic syndromes, but in our results there seemed to be no significant differences in specific pattern of the acyl compositions between the different test groups.

Variation of phospholipid oxidation and degradation products between control and diabetic zebrafish

Since the variables that elevated in diabetic zebrafish mainly comprised of phospholipid oxidation and degradation products based on the heat map (Figure 2), the sum of abundance for each related phospholipid class was calculated, and relative intensities of the three groups in 1-month and in 7-month were compared subsequently. As one of the major product of lipid peroxidation, PC-OOH evaluated in HBG (to 3.16-fold after 1-month overfeeding, and to 4.09-fold after 7-month overfeeding, respectively) (Figure 3A). It is reported that lipid hydroperoxides act as toxic mediators and relates to various of pathologic effects, e.g. PC-OOH accumulation in the plasma is involved in diabetes as well as hyperlipidemia, Alzheimer’s disease, and other metabolic diseases. Our result of PC-OOH was in favor of Nagashima et al., who demonstrated that PC-OOH in serum was increased in type 2 diabetic patients. While for the other detected hydroperoxide class, PE-OOH, the variation between groups seemed similar (for 1-month: 1.11-fold in MBG, 1.28-fold in HBG; and for 7-month:
1.36-fold in MBG, 1.33-fold in HBG) (Figure 3B). The levels of phospholipid oxidation and degradation products presented no obvious difference between short-term (1 month) and long-term (7 months) groups of overfeeding, which fit the data of fasting blood glucose levels. It seems that phospholipid oxidation might be related to the development of hyperlipidemia and diabetes.

As the end product of PC oxidation reaction, PC-CHO also increased significantly in this experiment. After 1 month’s overfeeding, the sum of these aldehydes increased to 1.35 and 3.31-fold in MBG and HBG, respectively. And for 7 months’ overfeeding, the values got higher (2.21 and 4.25-fold, respectively) (Figure 3C). There are quite few reports on PC-CHO variation in hyperglycemia up to now, although it is considered as oxidation product of PC. Continuous researches have been done by Itabe et al. since 20 years ago, who focused on the analysis of PC-CHO and other PC oxidation products in oxidized lipoprotein, and demonstrated them as chemical markers of oxidative stress.\textsuperscript{38–40} In addition, Nakanishi et al. found that all of the PC-CHO species together with other ox-PC were in higher amounts in the ischemic myocardium than in the non-ischemic myocardium, indicating the correlation between these oxidized phospholipids and oxidative stress-related diseases.\textsuperscript{41} A recent study by Khoury et al. successfully identified a diversity of phospholipid aldehydes. The achieved results enriched the oxidized phospholipids information for databases, and the authors proposed it as the strategy of analyzing these new biomarkers.\textsuperscript{18} In our study, PC-CHO showed the consistent tendency with PC-OOH, supporting the oxidation and degradation pathway
in type 2 diabetes mellitus.

Lysophospholipid also showed a comparable increase at the same time. For total lysoPC, 1-month of overfeeding resulted in 1.51-fold in MBG and 2.12-fold in HBG, while 7-month of overfeeding resulted in 1.86 and 2.44-fold, respectively (Figure 3D). A similar pattern was observed for lysoPE and lysoPI (Figure 3E and 3F). Our results are in accordance with that of Ha et al., who disclosed 6 lysoPC and 2 lysoPE species that significantly increased in male subjects with newly diagnosed type 2 diabetes mellitus. Besides, the present result of PS level elevation in MBG and HBG (Figure 3G) agreed with Lappas et al., who reported that PS served as one of the significant risk factors for the development of type 2 diabetes mellitus in women with a previous history of gestational diabetes. Within these series of lipid molecules, the most representative species as potential diabetic biomarkers is to be discovered.

**LysoPC20:5 and lysoPC22:6 as potential diabetic biomarkers**

To reveal potential key phospholipid species differences between normal group (Con) and the diabetic group (MBG + HBG), OPLS-DA was performed based on the EIC peak area from phospholipid profile after Pareto scaling and mean-centering, and the S-plot was generated (Figure 4A). The X-axis represented the contribution to the group differences of a particular variable, while the Y-axis indicated the confidence of the variable’s contribution. The top two important variables were marked in the S-plot, which were identified as lysoPC 20:5 (Figure 4D) and lysoPC 22:6 (Figure 4E) by MS/MS data. Taking lysoPC 20:5 as an example, HR-MS gave the singly charged
[M + H]$^+$ signal of $\text{C}_{28}\text{H}_{49}\text{O}_{7}\text{NP}^+$ ion with $m/z$ 542.3236 (calculated: 542.3241, $\Delta$ppm $= -0.92$). The MS$^2$ gave two characteristic peaks at $m/z$ 524.5 and $m/z$ 184.5, which were assigned as $[\text{M + H} - \text{H}_2\text{O}]^+$ and the PC head group, respectively. And the MS$^3$ of precursor ion $m/z$ 524.5 gave the continuous fragmentation of trimethylamine cleavage ($m/z$ 465.3) and acyl cleavage ($m/z$ 181.3). These diagnostic ions contributed to a certain identification.

The relative content variations among the three groups were observed (Figure 4B and 4C). LysoPC 20:5 increased to 2.35-fold for MBG and 3.05-fold for HBG after 1 month’s overfeeding, and 2.66-fold/3.45-fold after 7 months. While the significant increase of lysoPC 22:6 expressed 1-month 1.45-fold/2.03-fold and 7-month 1.57-fold/2.15-fold, respectively. The two lysoPC species showed no significant difference between 1- and 7-month’s overfeeding, which was in accordance with other phospholipid oxidation and degradation products as well as fasting blood glucose levels. There have been several studies that found lysoPC 18:2 as a target in human diabetic diagnosis, while Wang et al. demonstrated lysoPC 16:0 and lysoPC 18:0 as potential biomarkers for distinguishing the diabetic patients. The present result was in consistent with those investigations in terms of phospholipid class, but differed in molecular species. This may be due to the diversity of fatty acid composition in different animals (or in human). Fang et al. investigated the atherogenic zebrafish larvae by high-cholesterol diet feeding, to characterize 18:0, 18:1, 20:5, and 22:6 as significantly elevated lysoPC species. Despite the varieties of animal overfeeding, the
current work suggested that lysoPC acted as a meaningful chemical indicator toward oxidative stress-related metabolic diseases. The subsequent research design could include the oxidized phospholipid variation among different experimental objects (including diabetic patients), and the exploration/validation of oxidized phospholipid profile variation/reverse by certain diabetic treatment.

To the best of our knowledge, there is very limited investigation of lipidomic analysis in type 2 diabetes mellitus model zebrafish. In terms of lipidomic studies on diabetic samples, factors such as the polar head group, the linkage and unsaturation degree of the acyl chains, are accepted as important roles in diabetes, obesity, and other cardiovascular diseases, since they influence the biophysical properties of cellular membrane, including membrane fluidity.\(^{35}\) On the other side, oxidative stress is known to take crucial part in diabetes, which not only involves in these pathological processes above, but also results in the oxidation of phospholipid which participates in wide-ranging physiological processes. As the initiation of chain reaction, ROS attacks the unsaturated fatty acyl in the phospholipid, producing a variety of oxidized structures, such as phospholipid peroxides and their cleavage products aldehydes. The oxidized phospholipids are degraded to lyso-PL under the enzyme catalysis by phospholipase.\(^{48,49}\) Thus, the putative process of phospholipid peroxidation and degradation, which related to oxidative stress in diabetic zebrafish, was uncovered (Figure 5). Along with the fact that oxidized phospholipids are increasingly recognized as markers of oxidative stress and of various diseases associated with inflammation,
the current work suggested that oxidized phospholipids and the related products accumulated because of ROS attack, which fit the theory that a high degree of oxidative stress happens in the pathogenesis of diabetes.

Conclusion

In summary, the lipidomic analysis of phospholipids variations in type 2 diabetes mellitus model zebrafish plasma is systematically studied in the present work. The oxidative stress-related oxidized phospholipids (PC-OOH, PI-OOH, PC-CHO) and phospholipid degradative products (lysoPC, lysoPE, lysoPI) exhibited significant elevation, which could be correlated to rising blood glucose levels. Among them, lysoPC 20:5 and lysoPC 22:6 were found as two potential biomarkers in diabetic zebrafish. Herein, these findings would help to gain further insights into type 2 diabetes mellitus. Furthermore, using these potential targets as clinical parameters might contribute to the screening of the promising antioxidant agents for diabetic therapies.
