An ion-pair chromatographic method for separation of enantiomers of nomifensine maleate was established. Chiral separation was achieved by chromatography for N-trifluoroacetylated nomifensine maleate enantiomers on Supherisorb Silica 5 µm, a normal phase column, using a mixture of chloroform, methanol and water (100:3:0.15) containing a chiral counter ion, (+)-camphor-10-sulfonic acid (2x10^{-3} mol l^{-1}) as the mobile phase. The standard curve obtained was straight line passing through the origin; this extended from 25 ng to 25 µg of the injected material. The results suggested that the proposed method is simple and rapid enough to be applied for the purity test of nomifensine maleate enantiomers.

Keywords Nomifensine maleate, optical resolution, ion-pair chromatography, optical purity, (+)-camphor-10-sulfonic acid.

A number of pharmaceutical drugs have asymmetric carbon atoms in the molecules. The optical forms, d and l, of these atoms result in different pharmacokinetic parameters for absorption, metabolism and excretion. However, most of those drugs have been used as racemates because of difficulties in optical resolution and asymmetric synthesis. To examine the differences in the in vivo kinetics and pharmacological effects among enantiomeric drugs, establishment of a method to separate the enantiomers is a prerequisite.

Nomifensine maleate (8-amino-1,2,3,4-tetrahydro-2-methyl-4-phenylisoquinoline maleate) is a novel antidepressant. It has an isoquinoline structure, which is different from the three-membered ring system found in conventional antidepressants. Nomifensine maleate has an asymmetric carbon atom at the 4-position. The d-form is much more potent than the l-form in the synaptosomal catecholamine uptake, an index for evaluation of an antidepressive effect.

We have applied high performance liquid chromatography (HPLC) to measure the optical purity of nomifensine maleate enantiomers used for in vivo kinetic study or for evaluation of pharmacological effects.

Conventional methods for separation of enantiomers by HPLC can be classified into two: 1) the direct method, in which enantiomers are chromatographed with chiral stationary or mobile phases, such as a mobile phase containing amino acid-copper sulfate, chiral counter ion or β-cyclodextrin, a stationary phase combined with crown ether, π-electron receptor or hydrogen bonding reagent or with a Cu(II)-containing mobile phase with an L-amino acid-bonded stationary phase and 2) the indirect method in which the diastereomers formed from enantiomers with a chiral reagent are chromatographed with an ordinary stationary phase and mobile phase using optically active isocyanate, amino acid derivatives and carboxylic acid as a chiral agent. The indirect method has a wider applicable range than the direct method and is suitable to analyses with high sensitivity. However, the indirect method has disadvantages in that optically pure reagents are required for the formation of diastereoisomers. We tried to derivatize nomifensine maleate with various chiral reagents, but could not separate its enantiomers. This difficulty may be ascribable to the distance between the asymmetric carbon atom at the 4-position and the amino group at the 8-position. Optical resolution of nomifensine maleate enantiomers could not be attained by use of chiral stationary phases. So we tried to establish a rapid and simple, direct method using a chiral mobile phase containing (+)-camphor-10-sulfonic acid as counter ion and a column of ordinary silica.

Experimental

Apparatus
The pieces of apparatus used were a JASCO (Tokyo,
Japan) high performance liquid chromatograph (model BIP) equipped with a detector (model UVIDEC 100–IV) and a JASCO polarimeter (model DIP-181).

**Materials**
Nomifensine maleate (racemate) was obtained from Hoechst AG (FRG). Needed amounts of (+)-camphor-10-sulfonic acid and trifluoroacetic anhydride (TFAA) were purchased from Tokyo Kasei (Tokyo, Japan). Pentfluoropropionic anhydride (PFPA) and heptafluorobutyric anhydride (HFBA) were purchased from Gas-Chro Kogyo (Tokyo, Japan) and Nakarai Chemicals (Kyoto, Japan), respectively. All solvents for HPLC were products of E. Merck (Darmstadt, FRG). N-(p-Nitrobenzoyl)-l-glutamic acid was prepared by the usual method. N-Benzenesulfonyl-l-glutamic acid was synthesized as described in the next paragraph. Other reagents used were of analytical grade.

**Synthesis of N-benzenesulfonyl-l-glutamic acid**
A 73.5 g portion of L-glutamic acid was dissolved in 500 ml of 1 mol l⁻¹ HCl, and 84.5 g of calcium oxide was added. Then, 90.0 g of benzenesulfonyl chloride was slowly added dropwise under reflux; this reflux was continued for about 2 h. After cooling, the mixture was acidified with conc. HCl, then extracted with four portions of ethyl acetate. The organic phase was treated with anhydrous Na₂SO₄ and activated charcoal. Removal of ethyl acetate gave 84 g of the title compound (yield: 59%). mp: 135 - 136°C.

**Resolution of racemic nomifensine maleate by fractional crystallization**
To 35.4 g of nomifensine maleate (racemate), 350 ml of 1 mol⁻¹ NaOH was added. After extraction with 500 ml of ether, the ether layer was washed with water. After the ether was evaporated, 350 ml of N-benzenesulfonyl-l-glutamic acid aqueous solution (28.7 g–350 ml) and 200 ml of ethanol were added to the residue, and the mixture was stirred at room temperature.

The precipitate was collected by filtration and recrystallized from water. Then, 150 ml of 1 mol⁻¹ NaOH was added to the crystals and the mixture was extracted with 300 ml of ether. After the ether was evaporated, maleic acid–ethanol solution was added to the residue to produce the corresponding salt. Recrystallization from ethanol–water mixture (2:3) gave d-nomifensine maleate.

Two hundred milliliters of 1 mol⁻¹ NaOH was added to the filtrate, and the mixture was extracted with 300 ml of ether. After the ether was evaporated, an ethanol solution containing 29.6 g of N-(p-nitrobenzoyl)-l-glutamic acid was added and the mixture was refluxed. After cooling, insoluble crystals were collected by filtration and recrystallized from water. After addition of 150 ml of 1 mol⁻¹ NaOH, the crystalline precipitate was extracted with 300 ml of ether and the ether was evaporated. Maleic acid–ethanol solution was added to the residue to produce the corresponding salt, which was recrystallized from ethanol–water mixture (2:3) to give l-nomifensine maleate.

**HPLC condition**
Column, Supherisorb Silica 5 μm (250 mm×3.6 mm i.d., Harwell, England); mobile phase, a mixture of chloroform, methanol and water (100:3:0.15) containing (+)-camphor-10-sulfonic acid (2×10⁻³ mol l⁻¹); flow rate, 1 ml/min; and detection, UV 254 nm.

**Preparation of sample solutions for HPLC**
To 8 mg of nomifensine maleate, 0.2 ml of an acylating reagent (TFAA, PFPA or HFBA) was added and the mixture was stirred at room temperature for 10 min. Excess reagent was evaporated off under nitrogen gas flow at 40°C. The residue was dissolved in 2 ml of the mobile phase and 5 μl of the solution was subjected to HPLC.

Results and Discussion

Organic solvent in mobile phase

The chromatographic separation of N-trifluoroacetyl-nomifensine maleate enantiomers with various mobile phases is given in Table 1. When ethyl acetate was used as the main solvent, the enantiomer peaks exhibited tailing and were not resolved. Chloroform separated the enantiomer peaks better than dichloromethane. N-Trifluoroacetyl-nomifensine maleate did not elute with chloroform containing acetonitrile or tetrahydrofuran as the polar solvent, while chloroform containing methanol gave the most complete separation.

Acylating reagent and content of methanol in mobile phase

The separation of TFAA-, PFPA- or HFBA-acylated nomifensine maleate enantiomers was examined by use of a chloroform-methanol series as the mobile phase.

- As the methanol content increased, nomifensine maleate enantiomers acylated with each of the 3 acylating reagents exhibited smaller and smaller values of the capacity factor ($k'$), i.e., retention time, and of the resolution ($R$). N-Trifluoroacetyl-nomifensine maleate enantiomers could not be separated successfully at any of the methanol contents used.
- The methanol content was fixed at 3% so that the analysis might terminate within 20 min.

Effect of water in mobile phase on resolution

The proposed method is based upon the optical resolution of diastereometric ion pairs formed from N-trifluoroacetyl-nomifensine maleate enantiomers with (+)-camphor-10-sulfonic acid. The effect of water in the mobile phase on the optical resolution was examined (Fig. 2).

A: recrystallization, 3 times.
B: recrystallization, once.

As the water content increased in the mobile phase, the resolution was raised; it reached a maximum at 0.15 - 2.0%. The most suitable content of water was determined to be 0.15%.

Content of (+)-camphor-10-sulfonic acid

Figure 3 shows the effect of the content of (+)-camphor-10-sulfonic acid in the mobile phase on the optical resolution. A maximum resolution was obtained at 2×10⁻³ mol l⁻¹ of (+)-camphor-10-sulfonic acid.

Chromatogram and standard curve

The chromatogram of N-trifluoroacetyl-nomifensine maleate enantiomers obtained by the present system is given in Fig. 4. The standard curves of d- and l-forms were linear in the range 25 ng - 25 µg, passing through the origin.

Practical application

The optical purity of d- and l-nomifensine maleate obtained by fractional crystallization with L-glutamic acid derivative was determined by the proposed HPLC system. As shown in Table 2, the optical purity could be measured more accurately by the proposed method than the method using optical rotation as parameter. The proposed system is applicable to the purity test for nomifensine maleate enantiomers.

The detection limit of nomifensine maleate enantiomer by this method was 25 ng of the injected material. A further study is in progress on how to improve the proposed method for the determination of trace nomifensine maleate enantiomers, for evaluation of in vivo kinetics.
