The results of several pulmonary resections using a uniportal approach have been published. However, there are no reports of uniportal thoracoscopic anatomic segmentectomy in Japan. We have a fundamental belief in “reduced-port surgery” and therefore routinely perform uniportal thoracoscopic surgery for patients with pneumothorax. This report describes a successful case of uniportal thoracoscopic anatomic segmentectomy through a 3.5-cm incision in a 76-year-old woman with primary lung cancer. The patient was pathologically diagnosed with multiple primary adenocarcinomas stage IA (T1aN0M0). Postoperatively, no analgesics were needed. The operative procedure is described in detail and includes technical tips such as the pulley method, extra-vessel exposure, the shaft-on-shaft technique, one-hand encircling, and one-hand exposure. The selection criteria for uniportal thoracoscopic segmentectomy limit its use.

Keywords: pulmonary segmentectomy, single incision, thoracoscopic surgery
All four nodules, including one 6-mm, one 8-mm, and two 11-mm nodules, were located in the basal segment of the left lower lobe. These findings suggested a multiple primary lung cancer rather than recurrence of previous lung cancer based on the previous postoperative pathology and the appearance of GGO. 18F-fluorodeoxyglucose positron emission tomography-CT (PET-CT) demonstrated that hilar and mediastinal lymph nodes were negative for metastasis.

Surgical rather than medical treatment was chosen despite the presence of an epidermal growth factor receptor mutation in the tumor, because of the patient’s preference for surgical intervention and well-preserved pulmonary function. Pulmonary function tests revealed a vital capacity of 1.2 L (55%) and a forced expiratory volume in 1 s of 1.2 L (100%).

In general, the instrumentation of conventional VATS is also used for uniportal VATS. Instruments are preferably long and curved to allow for simultaneous insertion of two or three instruments. In addition, a 5-mm flexible thoracoscope (HD Endo EYE, LTF-VH; Olympus, Tokyo, Japan) and an energy device (ENSEAL™ TRIO; Ethicon Endo-Surgery, Cincinnati, Ohio, USA) are used during the surgery. In the present case, the patient, under general anesthesia with double-lumen intubation, was placed in the full lateral decubitus position with slight flexion of the table at the level of the mid-chest. The operator and the thoracoscope assistant stood on the anterior and posterior side of the patient, respectively. The scope was placed on the posterior side and the other working instruments were placed on the anterior side. When needed, the surgical table was rolled forward or backward to secure the operative field.

A 3.5-cm incision was made in the sixth intercostal space on the anterior axillary line (Fig. 1B). The incision was protected with a polyurethane wound retractor (Alexis wound retractor; Applied Medical, Rancho Santa Margarita, California, USA).

After deflating the lung, the pulmonary basal artery and vein were defined and divided with an articulated endoscopic stapler. We arbitrarily bend an articulated stapler to assist with stapler placement. We achieve optimal angles for stapler insertion into vessels with adequate exposure. We retracted the piece of silicone tape encircling the vessel across the pulmonary vessel to facilitate insertion of the stapler when there is a difficult angle (Fig. 2A). We prefer an Endo GIA™ curved tip with a gray-colored, 30-mm-long stapler (Endo GIA™ Ultra Universal and Curved Tip Articulating Vascular Cartridge; Covidien Surgical, Norwalk, Connecticut, USA) for the approach to pulmonary vessels rather than a conventional straight stapler for uniportal VATS. This avoids damage to the back or the other side of the vessel in a limited space because the curved tip has a slim and forward-jutting jaw. Additionally, adequate exposure of the vessel periphery facilitates insertion of the stapler because the insertion angle of the stapler increases (Fig. 2B).
left lung was deflated. This maneuver kept the affected segment expanded, resulting in the identification of the intersegmental plane (Fig. 3A). Next, we cut the lung parenchyma 1–2 cm deep from the surface along the inflation–deflation line using electrocautery. With this line as a landmark, the remaining lung parenchyma was dissected with a stapler proximal to the incision and then distally (Fig. 3B).

Finally, the basal segment was removed in a plastic bag through the incision using the vacuum-packing method. Then, the affected bronchus was isolated and encircled, and the endoscopic stapler was inserted around the basal bronchus. We prefer a blue-colored 45-mm long stapler (Echelon Flex™ ENDOPATH® Stapler; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio, USA) for the approach to the basal segmental bronchus because it helps to ensure more consistent thickness of the targeted tissue (pre-compression). After the anesthesiologist inflated the left lung, the segmental bronchus was divided and the remaining
Co., Ltd., Kyoto, Japan) to prevent air leakage. Lymph nodes 12l (lobar) and 13 (segmental) were also sampled. A 19-F silicone chest drain was placed through the incision. The operative time was 180 min, and blood loss was less than 30 mL.

The postoperative pathological findings demonstrated primary pulmonary adenocarcinomas in situ (11 and 10 mm) and focal adenomatous hyperplasia (5 and 6 mm) in the basal segment of the left lower lobe (pTisN0M0, staged as stage 0 [zero], complete resection). No analgesics were administered postoperatively. The chest tube was removed on postoperative day (POD) 2 and the patient was able to walk around the hospital ward. However, the patient developed acute respiratory distress syndrome (ARDS) on POD 3. The patient underwent intensive treatment, recovered, and was discharged 3 months after the onset of ARDS.

**Discussion and Conclusion**

Technically speaking, the most challenging aspect of uniportal VATS segmentectomy is identification of the intersegmental plane. Two previous reports of uniportal VATS anatomic segmentectomy have been published. Gonzalez-Riva, et al. and Wang, et al. reported 17 and five cases, respectively, but they did not describe how the intersegmental plane was identified. It is possible that in these previous reports the authors were able to complete the uniportal procedure in a manner similar to conventional multi-port VATS. However, this seems unlikely because there was no angle for insertion of the endoscopic staples into the segmental plane. Therefore, in the case reported here, the intersegmental plane was dissected proximal to the incision and then distally. In addition, a 4- to 5-cm incision seems too large to be considered uniportal VATS because such an incision is large enough to allow for direct visualization and anatomic pulmonary segmentation.

We generally do not use specialized instrumentation even when uniportal VATS is introduced. The use of conventional instruments for retraction and dissection during uniportal VATS is possible. However, additional procedural modifications are required to allow for simultaneous insertion of two or three instruments; we prefer to use the following unique techniques:

**Shaft-on-shaft technique (Fig. 1B):** We create a pivot point using a right-handed instrument during the shaft-on-shaft technique. Specifically, we hold the shaft of the right-handed instrument (e.g., scissors, an energy device, or a vacuum) against the shaft of a left-handed instrument (e.g., a grasper or a sponge stick) at the edge of the access incision.

**One-hand encircling:** The vessels and bronchi are encircled with a piece of silicone tape with one hand because excessive use of instruments crowds access to the incision. We use forceps to grasp the portion of the silicone tape distant from the tip in the long-axis direction and pass the forceps through the vessel. The tip of the silicone tape is then bent, and the silicone tape subsequently straightens. Finally, we release the silicone tape, pull the forceps, and grasp the tape again from the other side of the vessel.

**One-hand exposure:** We prefer to secure exposure of the operative field with one hand (the nondominant hand). We regrasp the more distal part of the initial position when the pulmonary parenchyma obstructs the visual field of the thoracoscope. Moving the entire lung parenchyma out to expose the visual field is not required during VATS. Exposing the direct path of the instruments is adequate.

When considered geometrically, the approach for a target lung lesion is similar to a coaxial approach. That is, surgeons are working with their eyes and hands in the same plane (co-axial setup), much like open surgery and in contrast to three-port VATS (para-axial setup). Interestingly, the principles of conventional open surgery are helpful when performing uniportal VATS. However, the principles of conventional surgery may be difficult to implement for surgeons who have experience with only VATS.

Our criteria for uniportal VATS segmentectomy include stage IA lung cancers smaller than 2 cm in diameter, GGO, peripheral tumors, metastatic lung cancers, and the preservation of pulmonary function in cases of benign tumors. Specifically, we began performing the uniportal VATS major pulmonary resection without mediastinal lymph node dissection for the lower lobes because those presented less difficulty. The absence of lymph node involvement is always confirmed preoperatively by CT and PET-CT.
