Iatrogenic aortic valve perforation during non-aortic cardiac operations is a rare complication. The suture-related inadvertent injury to an AV leaflet can produce leaflet perforation with aortic regurgitation after ventricular septal defect repair (VSDR). We report three consecutive patients who had iatrogenic aortic leaflet perforation during VSDR in other hospitals and referred to our hospital for reoperation. In all three cases, the perforated AV leaflets were preserved and repaired by autologous pericardial patch or direct local closure.

Keywords: iatrogenic aortic valve perforation, ventricular septal defect repair, surgical complication

Introduction

Iatrogenic valvular regurgitation has been reported after different cardiac procedures as a result of leaflet perforation or entrapment.\(^1\)\(^2\) Iatrogenic aortic valve (AV) perforation during non-aortic cardiac operations is a rare complication. The suture-related inadvertent injury to an AV leaflet can produce leaflet perforation with aortic regurgitation (AR) after ventricular septal defect repair (VSDR).\(^3\)\(^4\) This injury results from the immediate anatomic vicinity of the AV, especially the right coronary leaflet and noncoronary leaflet. New onset of AR after a repair procedure on ventricular septal defect (VSD) can be the direct consequence of aortic leaflet perforation caused by the stitches. This risk may be greater with inexperienced surgeons in lower-level hospitals. In this report, we described three consecutive patients who suffered AR after VSDR. In all the cases, AV perforation was repaired by autologous pericardial patch or direct local closure.

Case Report

From 2013 to 2015, three patients (Table 1) who presented with a new onset of AR after VSDR in other hospitals were referred to our hospital. All three patients successfully underwent reoperation in our institution. The interval between VSDR and the reoperation for repair of aortic perforation ranged from 7 to 12 years. All three patients had simple closure of a membranous VSD previously in other hospitals. None of these patients had a history of endocarditis or chest trauma. Physical examination revealed a diastolic murmur over the aortic valvular area. Chest X-ray showed an enlarged cardiac silhouette and a normal pattern of pulmonary vascularility. Electrocardiogram revealed sinus rhythm with/without complete right bundle branch block. Transthoracic echocardiography (TTE) showed AV perforation in the noncoronary leaflet near the annuli. The length of the leaflet tear ranged from 4 to 6 mm. The left ventricles were dilated with the left ventricular end-systolic dimension index (LVESDI) >25 mm/m\(^2\) (Table 2). The left ventricular (LV) systolic functions were normal in all three patients.
All the operations required standard cardiopulmonary bypass through median sternotomy. The AV was inspected through a standard aortotomy incision. In all the cases, redo operation revealed that the AR resulted from perforation of the noncoronary leaflet was close to the annulus (Fig. 1). The length of the leaflet tear ranged from 4 to 6 mm. AV repair was attempted in all cases. The first and second patients with a 4 mm perforation were closed with two interrupted 5-0 Prolene sutures (Ethicon US, LLC., Somerville, NJ, USA) with pericardial pledgets to buttress the suture (Fig. 2). The third case with AV perforation of 6 mm in length could not be directly sutured. To cover the tear, an autologous pericardial patch was trimmed according to the size of the perforation, and sutured with a 6-0 Prolene continuous suture (Ethicon US, LLC., Somerville, NJ, USA).

All patients recovered from the redo operation uneventfully. On discharge, two patients had competent AVs without regurgitation, and the other patient had trivial AR. During the follow-up, TTE performed at 1 year showed no significant AR in all three patients, and normal left ventricular dimensions were restored.

**Discussion**

Iatrogenic AV perforation following cardiac operations is a rarely reported complication.\(^1,2\) AV perforation after VSDR is rare and mostly studied as the case reports.\(^4-7\) We report three consecutive patients who suffered significant aortic leaflet injury in the noncoronary leaflet during VSDR procedure and referred for reoperation in our institution.

Iatrogenic Aortic Valve Perforation

and a new AR was observed after VSDR. So iatrogenic AV perforation was diagnosed by history of previous VSDR procedure and the typical echocardiographic findings in the three patients.

Proper management of the iatrogenic complications by the surgeon is important. The increased awareness of the complication results in avoidance of adverse surgical results while performing VSD repair, and improves the ability to repair iatrogenic leaflet perforation. AV repair is most commonly performed in patients with severe AR due to AV leaflet perforation. The repair methods include direct local closure and patch repair of the leaflet perforation using autologous pericardium. In all cases presented, valve repair was performed, leading to excellent functional and clinical outcomes. This finding is in agreement with other reports demonstrating that repair of aortic leaflet perforation offers the satisfactory results. This report consequently demonstrates that AV preservation should be striven for as the procedure of choice.

Even if AV injury during a VSDR procedure is a rare complication, any new AR should alert the surgeon to be aware of this deterioration. More attention should be paid to the rare complications, and proper imaging techniques employed for diagnosis so as to intervene as soon as possible. Continuous monitoring and documentation of AV function after a VSDR procedure is mandatory. In mild or moderate AR, careful observation is justified, while bearing in mind the risk and extent of redo operation. The iatrogenic AV leaflet injury may present after a long time with progressive AR in majority of the patients. As time passed, the patient’s heart gradually dilated, and reoperation to repair the AV perforation was inevitable. When AR is severe and heart enlargement is detected on TTE after the VSDR operation, this injury can necessitate redo-operative repair of the aortic leaflet. Otherwise, the relevant AR can lead to impairment of left ventricular function over time, thereby placing the patient at additional risk. The first and third patients were found to have significant AR at 6, and 11 years postoperatively, whose left ventricle was significantly dilated with the LVESDI >25 mm/m² although the patients did not have significant symptoms. It is class IIa recommendation for AV replacement in 2014 American Heart Association (AHA)/American College of Cardiology (ACC) valvular heart disease guideline, so redo operation was indicated.

From 2013 to 2015 at our center, we admitted three patients who had suffered from an iatrogenic AV injury after VSDR. We believe that the incidence of iatrogenic AR after a VSDR procedure may be higher than previously reported. So we suspect that there is still a fraction of patients who have mild AR due to iatrogenic leaflet defect do not receive treatment upon proper evaluation. The AR may be underdiagnosed or remain undetected on discharge, and very small perforations can enlarge over time. As the first operations for VSD in the three patients were performed in other hospitals, the lack of longitudinal observation of AR was the main flaw in our report.

Conclusion

Aortic leaflet injury is an infrequent but severe complication of VSDR. Because of the serious consequences, it should be mentioned in the informed consent process. We report three consecutive patients who suffered AR after VSDR. In all cases, the AV perforations were repaired by autologous pericardial patch or direct local closure. The valve preserving repair of the injury is feasible with excellent clinical and functional midterm results.
