A 65-year-old man infected with human immunodeficiency virus underwent emergency surgery for rupture of a mycotic descending thoracic aneurysm. The aneurysm was replaced with a prosthetic graft wrapped with omentum. Esophageal perforation occurred 3 weeks after surgery. The patient’s condition remained stable, and we adopted a conservative treatment. The esophageal fistula had not healed completely and a biopsy of the scar revealed gastric cancer. We performed a distal gastrectomy, Roux-Y reconstruction, and enterostomy for enteral feeding. Follow-up endoscopy revealed healing of the fistula, and the patient was eventually discharged. We managed this potentially fatal complication with minimally invasive treatment.

Keywords: esophageal perforation, aneurysm rupture, human immunodeficiency virus

Introduction

The incidence of infection by human immunodeficiency virus (HIV) in surgical patients has been increasing in recent years, and these patients develop systemic complications of HIV infection after surgery. In particular, HIV-infected patients have a higher risk of developing postoperative sepsis than do uninfected patients.1-3 As regards cardiovascular surgery, it is reported that procedure for aneurysm is associated with high mortality,11 however surgery with cardiopulmonary bypass seems to be acceptable.8 Delayed esophageal perforation secondary to thoracic aortic aneurysm rupture is rare, but still remains a fatal complication in spite of improvements in treatment. Therefore, early diagnosis and effective therapeutic management are mandatory.5-8 In case of esophageal resection, a gastric tube is usually used for esophageal reconstruction. Herein, we report a case of esophageal perforation secondary to thoracic aortic aneurysm rupture in a patient with HIV infection and gastric cancer.

Case Report

A 65-year-old man with a 10-day history of upper abdominal pain and fever was admitted to another hospital. He showed no abnormalities on physical examination with the exception of a low-grade fever. On laboratory examination, the white cell count was 9000/µl and C-reactive protein level was 21 mg/dl. On serological testing, HIV antibody was positive and the CD4 T-cell count was 72 cells/µl; however, a HIV viral load was not detected. Abdominal X-ray...
showed no abnormalities such as free air; however, abdominal computed tomography (CT) revealed splenomegaly and an unknown lesion around the esophagus. Upper gastrointestinal (GI) endoscopy demonstrated an ulcer scar at the stomach angle, and extrinsic esophageal compression was detected 30 cm away from the incisors toward the esophagocardial junction. Three days after admission, he developed chest pain. Chest CT showed a 6.5-cm saccular aneurysm of the descending aorta with an irregular aortic wall and a large mediastinal hematoma compressing the esophagus (Fig. 1). Based on the radiological findings, clinical symptoms, and blood examination results, the patient was diagnosed with rupture of a mycotic descending thoracic aneurysm. He was then referred to our hospital, where he underwent an emergent surgery through a left posterolateral thoracotomy. An inflammatory lesion was present around the middle descending aortic aneurysm, and the aneurysm was adhered to the esophagus and lung. No disruption was found in the esophagus at that time. From these findings, the patient was diagnosed with rupture of a mycotic aneurysm, and the aneurysm was replaced with a prosthetic vascular graft wrapped with omentum to prevent infection of the implanted graft. The patient had an uneventful course without infection. However, a low-grade fever, mild leukocytosis, and increased C-reactive protein level developed 3 weeks after surgery. CT showed extra-esophageal air and fluid collection in the posterior mediastinum (Fig. 2). Emergency upper GI endoscopy demonstrated mucosal necrosis and perforation of the esophagus to the mediastinal space 35 to 40 cm from the incisors (Fig. 3). Total parental nutrition was immediately started, and he was maintained with antibiotic coverage. Because his general condition was stable, we decided to perform conservative therapy. Upper GI endoscopy showed improvement in the esophageal necrosis, which decreased in size during the following 2 months. However, the esophageal fistula did not heal completely, and a biopsy of the scar revealed gastric cancer that showed a tendency to increase in size thereafter. He underwent a distal gastrectomy with D2 dissection (preservation of omentum), Roux-Y reconstruction, and enterostomy for enteral feeding. At the sixth postoperative month after the aneurysm surgery, follow-up upper endoscopy revealed healing of the fistula, and he was eventually discharged. He did well after discharge for 5 years, but died of pancreatic cancer without evidence of graft infection or recurrence of the gastric cancer.

**Discussion**

The number of HIV-infected patients has been increasing in the past decade. Such patients have a higher incidence of postoperative sepsis than do non-HIV-infected patients. Surgical treatment of HIV-related aneurysms is associated with high perioperative morbidity and mortality. The rate of hospital mortality associated with cardiac surgery in HIV-infected patients ranges from 0% to 40%. Surgery with cardiopulmonary bypass does not seem to accelerate the immunodeficiency and is acceptable. Because HIV-infected patients are immunocompromised and may have
Esophageal Perforation Following Aneurysm Rupture

had a low CD4 cell count and hypoalbuminemia; furthermore, we considered esophageal resection with colonic reconstruction to be a high-risk procedure. When such a radical procedure seems too risky, conservative treatment should be considered. It is possible to manage this fatal complication with conservative therapy in selected patients without evidence of infection.6–8) This patient’s general condition was stable, and the prosthetic graft was covered with omentum. We decided to adopt a conservative strategy. The total hospitalization duration for patients with esophageal perforation undergoing conservative therapy reportedly ranges from 3 to 90 days.7,8)

In our case, the esophageal fistula did not heal for a long time. HIV infection may cause esophageal mucosal cell dysfunction, which might delay mucosal cells repair.6)

Conclusion

This is the first reported case of delayed esophageal perforation secondary to thoracic aortic aneurysm rupture complicated with gastric carcinoma in an HIV-infected patient. The selection of minimally invasive treatment for this fatal combination of diseases highlights the importance of careful systemic risk assessment in these complicated patients.
