Methicillin-resistant Staphylococcus aureus (MRSA) is one of the major pathogens responsible for nosocomial infections. The presence of MRSA in a hospital is detrimental to patients and to hospital management. Thus, rapid identification of MRSA is needed. Here, we report on a prospective method to rapidly discriminate of MSSA from MRSA using matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) and support vector machine (SVM) analysis in 160 clinical isolates of S. aureus. The predictive model was tested using 100 S. aureus isolates (50 MSSA and 50 MRSA). The identification rates were 90.0% for MSSA and 87.5% for MRSA in a 10-fold cross-validation SVM. In blind test sets, 60 S. aureus isolates (30 MSSA and 30 MRSA) were correctly classified, with identification rates of 93.3% for MSSA and 86.7% for MRSA. The method proposed in this study using the predictive model enables detection of one colony in 5 minutes, and thus is useful at clinical sites at which rapid discrimination of MRSA from MSSA is required.

Key words : Rapid discrimination / MSSA / MRSA / MALDI-TOF MS / MALDI BioTyper software.

INTRODUCTION

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is increasingly used in clinical microbial diagnostics for species identification of pathogens (Nomura., 2015). Bacteria can be rapidly identified by comparing MALDI-TOF MS fingerprints to a database of reference spectra, and this technique has been used to identify microorganisms such as Gram-negative rods (e.g., Escherichia coli and other members of the Enterobacteriaceae family) (Camara et al., 2007), Gram-positive cocci (e.g., Staphylococcus aureus and Streptococcus) (Edwards-Jones et al., 2000), and some Gram-positive rods (e.g., Bacillus cereus) (Ryzhov et al., 2000). MALDI-TOF MS for identification of bacterial strains isolated from clinical samples has been examined in detail (Seng et al., 2009). In our laboratory, we prospectively assessed the performance of MALDI-TOF MS for identification of
bacterial strains that are routinely isolated from clinical samples. The identification rates at the species and genus levels were 91.7% (429/468) and 97.0% (454/468), respectively (Sogawa et al., 2011), and both rates were improved by adding clinical isolate data obtained in our laboratory to that in the original commercial database (Sogawa et al., 2012).

Methicillin-resistant *Staphylococcus aureus* (MRSA) is one of the major pathogens responsible for nosocomial infection. In Japan, MRSA was isolated from 59.7% of cases diagnosed with respiratory tract infections involving *S. aureus* in 2007 (Niki et al., 2009). Bacteremia due to MRSA in compromised patients has markedly increased morbidity and mortality compared to that caused by methicillin-susceptible *Staphylococcus aureus* (MSSA) infection (Weinstein et al., 1997; Wisplinghoff et al., 2004). Treatment of MRSA-linked bacteremia is also associated with higher hospital costs and longer hospitalization, compared to MSSA-linked bacteremia (Ben-David et al., 2009). Therefore, the presence of MRSA is detrimental to patients and to hospital management, and early detection and breaking of the infection route are important for preventing infection and reducing the prevalence of MRSA in hospitals. However, *S. aureus* is mostly detected in a cultured colony by examinations such as a coagulase test, and confirmation of MRSA requires a further 24 hours (Lowy., 2003). In the current work, we performed a prospective study of a method to discriminate of MSSA from MRSA using MALDI-TOF MS, with the goal of the rapid identification of MRSA.

**MATERIALS AND METHODS**

**Clinical samples**

A total of 160 *S. aureus* isolates were tested using MALDI-TOF MS over a 9-month period from October 13, 2013 to January 14, 2015 in Chiba University Hospital. The isolates were retrieved from clinical samples and identified in our laboratory at the species level in parallel with use of conventional methods. During the first six months, 100 *S. aureus* isolates (50 MSSA and 50 MRSA) (set 1) were subjected to MALDI-TOF MS analysis. The MALDI system results of pattern-matching are expressed as scores from 0 to 3, with a score <1.7 indicating unreliable identification; >1.7 indicating genus identification, and >2.0 indicating species identification. The isolates were successfully identified by the MALDI system with a score >2.0 and their spectral data were incorporated into the original database. Using the new algorithm (which we refer to as the MRSA algorithm), 60 *S. aureus* isolates (30 MSSA and 30 MRSA) (set 2) obtained in the next 3 months and 5 *S. aureus* isolates (4 MSSA and one MRSA) (set 3) transferred Gifu University School of Medicine Pathogenic Bacterial Resource Stock Center (GMGC) were tested. Each clinical specimen was plated on an appropriate agar plate (Chocolate Agar, Trypticase Soy Agar II with 5% sheep blood; Nippon Becton Dickinson Co., Tokyo, Japan), depending on the sample and in accordance with our laboratory procedures.

**MALDI-TOF MS**

To identify the isolates, MALDI-TOF MS was performed on a AutoFlex® II TOF/TOF mass spectrometer (Bruker Daltonics GmbH, Leipzig, Germany) with Flexcontrol™ software 3.0 (Bruker Daltonics) for automatic acquisition of mass spectra in the linear positive mode within a range of 2 to 20 kDa. The mass spectrometer was periodically calibrated using a Bruker Daltonics bacterial test standard (*Escherichia coli* extracts including additional RNase A and myoglobin proteins). Calibration masses were as follows: RL36, 4364.3 Da; RS22, 5095.8 Da; RL34, 5380.4 Da; RLmeth, 6254.4 Da; RL32, 6315.2 Da; RL29, 7273.5 Da; RS19, 10229.1 Da; RNase A, 13682.2 Da; myoglobin, 16952.5 Da. Automated analysis of the raw spectral data was performed using MALDI BioTyper automation 2.0 software (Bruker Daltonics) based on standard pattern matching using a library of 3,746 spectra (database updated on June 9, 2010) and the default settings.

A single colony was directly deposited on a MTP BigAnchorChip 384 TF target plate (Bruker Daltonics). The preparation was overlaid with 1 μl of α-CHCA matrix solution (a saturated solution of α-cyanohydroxycinnamic acid in 50% acetonitrile/2.5% trifluoroacetic acid). The colony was then air dried at room temperature to allow co-crystallization with the experimental sample. The process from MALDI-TOF MS measurement to identification was performed automatically without user intervention. Briefly, the software generated a list of peaks up to 100. The threshold for peak acceptance was a signal-to-noise ratio of 10. After alignment, peaks with a mass-to-charge ratio difference <250 ppm were considered to be identical. The generated peak lists
were used for matches against the reference library using the integrated pattern matching algorithm in the software. Results of pattern-matching are expressed as scores from 0 to 3, with a score <1.7 indicating unreliable identification; >1.7 indicating genus identification, and >2.0 indicating species identification (Sogawa et al., 2011; 2012).

Support vector machine (SVM) classification

SVM is a new machine learning approach originally proposed and developed by Vapnik (Liu et al., 2004). SVM applications are being pursued in areas from face recognition to genomics (Liu et al., 2006). SVM has been used to identify candidate molecular markers predicting chemotherapy resistance in non-small cell lung cancer (Han et al., 2010) and to analyze serum peptide/protein profiles in breast cancers (Fan et al., 2012). This approach could be a powerful tool for analysis of complex data from MALDI-TOF MS. We constructed a non-linear SVM classifier to discriminate between MRSA and MSSA. Visual evaluation of MALDI-TOF spectra was performed using FlexAnalysis 3.0 (Bruker Daltonics). For construction of the algorithm, raw spectra were processed using the SVM approach in MALDI BioTools 3.0.

Protein Identification

One colony was suspended in 300 µL of distilled RNase-free water. Absolute ethanol (900 µL) was added and mixed carefully, and then the sample was centrifuged (14,000 × g for 2 min). The supernatant was discarded and the pellet was air dried. Formic acid (70%; 25 µL) and acetonitrile (25 µL) were added to the pellet and mixed thoroughly, and then the sample was centrifuged again (14,000 × g for 2 min). Ten volumes of ice cold acetone were added to the supernatant (40 µL). Peptides/proteins were allowed to precipitate at -20°C for 2 h and then obtained by centrifugation (13,000 × g for 10 min at 4°C). After decanting of acetone, the peptides/proteins were air dried. The dried pellets were resuspended in buffer (0.1% trifluoroacetic acid in water, vol/vol) and further separated by reversed-phase HPLC in an automated HPLC system (Shiseido Nanospace SI-2, Shiseido Fine Chemicals, Tokyo, Japan).

The concentrated flow-through sample (75 µL) was directly loaded onto a Capcell Core C18 column (Shiseido). Reversed-phase separations for each flow-through fraction were performed using a multisegment elution gradient with eluent A (0.1% trifluoroacetic acid in water, vol/vol) and eluent B (0.08% trifluoroacetic acid in 90% acetonitrile, vol/vol). The gradient elution program consisted of three steps with increasing concentrations of eluent B (5% B for 5 min, 5% to 95% B for 23 min, and 95% B for 11 min) followed by 5% B for 21 min for re-equilibration of the column at a flow rate of 0.40 mL/min, with a total run time of 60 min. Based on the chromatogram recorded by measuring the absorbance of the eluate at 280 nm, fractions eluted at retention times between 19.1 and 39.1 min were collected in 40 0.2 mL aliquots at a fraction size setting of 0.5 min. Fractions including objective peaks were confirmed by MALDI-TOF MS. N-terminal amino acid sequence analysis was performed using a Procise 494 cLC protein sequencing system (Applied Biosystems, Foster City, CA, USA).

Immunoprecipitation

One colony was suspended in 300 µL of distilled RNase-free water. Absolute ethanol (900 µL) was added and mixed carefully, and then the sample was centrifuged (14,000 × g for 2 min). Supernatant was discarded and the pellet was air dried. Formic acid (70%; 25 µL) and acetonitrile (25 µL) were added to the pellet and mixed thoroughly, and then the sample was centrifuged again (14,000 × g for 2 min). Ten mg of antibody-fixed affinity beads (Shiseido) was bound with 10 µg of MRSA PBP2a monoclonal antibody (Abnova Corp., Taipei, Taiwan). Subsequently, 40 µL of supernatant was mixed with 100 µg of beads in 500 µL of 20 mM Tris-buffered saline at 4°C for 1 h. After centrifugation (3000 × g for 1 min at 4°C), the pellets were eluted with 100 µL of 100 mM glycine-HCl. The tube was placed in a Magnetic Separator and the supernatant was collected for further pretreatment with C18 Magnetic Beads (Bruker Daltonics).

RESULTS

Development of the discrimination algorithm

In the first set of 100 S. aureus isolates (50 MSSA and 50 MRSA), all were correctly identified at the species level with a score >2.0. The concordance of identification at the species level was 100.0% (100/100 isolates) compared with the conventional method. Visual evaluation of MALDI-TOF spectra was performed using FlexAnalysis 3.0 (Fig.1). After noise filtering and peak clustering, 128 peaks were detected in the MSSA and MRSA groups. All mass peaks were fed into the SVM and the accuracy of each combination for distinguishing MSSA from MRSA was analyzed. This model comprised 6 peaks with m/z of 1888.1, 1935.9, 2760.3, 2867.9, 3044.2, and 4641.3. The average intensities for the 6 peaks are shown in Table 1. For other peaks, there was no significant difference (p<0.05) between MRSA and MSSA. The predictive model was tested using 100 S. aureus isolates (50 MSSA and 50 MRSA). The identification rates were 90.0% for MSSA and 87.5% for MRSA following the 10-fold cross-validation SVM.

**Evaluation of the discrimination algorithm**

In the second set of 60 *S. aureus* isolates (30 MSSA and 30 MRSA), all were again correctly identified at the species level with a score >2.0. The concordance of identification at the species level was 100.0% (100/100 isolates) compared with the conventional method. In the blind test sets, 60 *S. aureus* isolates (30 MSSA and 30 MRSA) were correctly classified, with identification rates of 93.3% for MSSA and 86.7% for MRSA (Table 2).

In the third set of 5 *S. aureus* isolates (4 MSSA and one MRSA), all were again correctly identified at the species level with a score >2.0. The concordance of identification at the species level was 100.0% (100/100 isolates) compared with the conventional method. Five

*S. aureus* isolates (4 MSSA and one MRSA) were correctly classified, with identification rates of 100.0% for MSSA and 100.0% for MRSA.

**Identification of the 3043 Da peptide**

Partial purification of the peptide corresponding to the 3043 m/z peak and N-terminal amino acid sequencing revealed that the 3043 Da peptide was a fragment of PBP2a (Fig. 2).

The intensity is very low in other 5 peaks, it could not be identified.

**Immunoprecipitation**

The PBP2a level in the supernatant was minimal when the MRSA isolate was incubated with antibody-fixed affinity beads coated with MRSA PBP2a monoclonal antibody and centrifuged (Fig. 3B), in contrast to the result for the MRSA isolate without antibody treatment.
RAPID DISCRIMINATION BETWEEN MRSA AND MSSA

167

venous catheter-associated bacteremia. MRSA was first isolated in the UK in 1961 (Jevons., 1961) and has now become prevalent worldwide, with few countries in which MRSA is not currently present (Yoshida et al., 2003). It takes approximately 18 hours to identify S. aureus from a cultured colony using conventional methods, whereas MALDI-TOF MS enables 5-minute identification from one colony. Therefore, this method shortens the time for reporting of results to clinical sites, thereby allowing earlier selection of drugs.

Use of MALDI-TOF MS to differentiate MRSA from MSSA was first reported by Edwards-Jones et al. (Edwards-Jones et al., 2000). Intact cell mass spectra of seven reference strains of MSSA, seven clinical isolates of MRSA, and six strains of CoNs were compared in a mass range of 500-10,000 m/z. Group-specific biomarker ions were identified in the lower mass range of 500-2000 m/z, which allowed correct differentiation of MRSA from MSSA (Edwards-Jones et al., 2000). Du et al. (2002) identified 74% of 76 S. aureus strains and MRSA was correctly distinguished from MSSA using cluster analysis with a dendrogram. Jackson et al. (2005) found that MSSA and MRSA in S. aureus isolates had different intensities of peaks at 3048 m/z, 3086 m/z and 3124 m/z, and Drake et al. (2011) showed that S. aureus isolates had strain clustering differences among community (n=12) and hospital-associated MRSA (n=14) and MSSA strain SS6 (n=18), based on the intensities of peaks at 2302 m/z and 3871 m/z. Among the 6 peaks we used to distinguish MRSA from MSSA in the present study, two (3043 m/z and

DISCUSSION

S. aureus is a major cause of hospital and community-acquired infections that can result in serious consequences (Diekema et al., 2001). Hospital infections caused by S. aureus include those affecting the bloodstream, lower respiratory tract, skin and soft tissues, as well as ventilator-assisted pneumonia and central

The intensity of the 3043 Da peak was markedly decreased.
4640 m/z) have been reported as important peaks for distinguishing MRSA by Jackson et al. (2005) and Wolters et al. (2011).

In this study, we conducted a prospective study of routine MALDI-TOF MS analysis using a predictive model. In the blind test, 60 S. aureus isolates (30 MSSA and 30 MRSA) were correctly classified, with identification rates of 93.3% for MSSA and 86.7% for MRSA. Among the 6 peaks in the predictive model, the 3043 m/z peak had the highest weight and average intensity, and was identified as a fragment of PBP2a. Resistance occurs following chromosomal acquisition of novel DNA, resulting in production of PBP2a, which has a low binding affinity for methicillin (Woodford et al., 2005). PBP2a substitutes for all other PBPs, and its low affinity for all β-lactam antibiotics confers resistance to these agents, including cephalosporins (Lowy et al., 2003). PBP2a is encoded by mecA, a part of the mobile genetic element in the staphylococcal chromosomal cassette mec (SCCmec) (Wolters et al., 2011). Intracellular proteins undergo repeated synthesis and degradation that cause turnover at a certain rate; however, the mechanism of PBP2a degradation by proteases is unknown. Clinical tests such as the coagulase test only permit identification of S. aureus in a cultured colony. A kit for MRSA detection based on PBP2a is available, but the method is complex and time-consuming. PCR-based assays (IDI-MRSA PCR, Xpert MRSA PCR, BD GeneOhm MRSA, and Xpert MRSA/SAT STI real-time PCR) require 1 to 4 hours from clinical sampling to obtaining results (van Hal et al., 2007; Rossney et al., 2008; Bischof et al., 2009; Wolik et al., 2009; Dubouix-Bourandy et al., 2011). In contrast, the method proposed in this study using a predictive model enables detection from one colony in 5 minutes, and thus could be useful at clinical sites at which rapid discrimination of MRSA from MSSA is required. It should be noted that the discrimination rate was not 100%, which is important at clinical sites, and further refinement of the procedures and databases are needed.
