The effects of administering the selenocompounds, sodium selenite, methylseleninic acid (MSA), and seleno-L-methionine (SeMet) on glucose tolerance were compared in the nicotinamide (NA) and streptozotocin (STZ)-induced diabetic mouse model. ICR mice were intraperitoneally treated twice with STZ (100 mg/kg) 15 min after an injection of NA (120 mg/kg) at a 1-d interval. Non-fasting blood glucose levels were then monitored weekly while orally administering the selenocompounds at 158 µg Se/kg body weight with free access to a selenium-deficient diet for 5 weeks. The mean body weights of NA/STZ-induced diabetic mice were partly restored by the administration of selenocompounds, while SeMet led to a higher selenium content and glutathione peroxidase 1 activity in the pancreas. Non-fasting and oral glucose tolerance-tested blood glucose levels, which were elevated by NA/STZ, were significantly suppressed by the administration of SeMet. These results suggest that SeMet may improve glucose tolerance in a NA/STZ-induced mild diabetic mouse model by increasing bioavailability in the pancreas.

Key words selenium; deficiency; diabetes; seleno-L-methionine; selenite; methylseleninic acid

Type 2 diabetes mellitus is a metabolic disease that develops as a result of defects in the secretion of insulin from pancreatic β-cells and actions of insulin on target tissues such as the liver, muscle, and adipose tissue. This disease is characterized by a diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nervous system, and is the leading cause of blindness, end-stage renal disease, and neuropathy. The development of this disorder has been linked to genetic and lifestyle factors, with obesity being the most common underlying factor. Even though type 2 diabetes is mostly preventable through lifestyle and diet modifications, its prevalence is expected to increase due to the worldwide obesity epidemic. Such deteriorations in lifestyle have also been linked to oxidative stress in the pancreas. The resulting enhancement in the production of reactive oxygen species (ROS) not only induces a dysfunction in pancreatic β-cells, but also inhibits insulin signal transduction and the actions of insulin, including increased glucose uptake and glycogen synthesis. However, development strategies to protect β-cells and insulin target tissues against oxidative stress may effectively prevent and treat type 2 diabetes. Therefore, an animal model needs to be established that is suitable for examining diabetes and its prevention. In the present study, we demonstrated that the ICR strain mouse was an appropriate animal model of nicotinamide (NA) and streptozotocin (STZ)-induced mild diabetes.

Selenium (Se) is an essential trace element for mammals and regulates many intracellular functions as a chemical component of selenoproteins. The well-known selenoproteins are Se-dependent enzymes that include the glutathione (GSH) peroxidase (GPX) family and thioredoxin reductase (TR) family, which have selenocysteine residues in the catalytic centers and function as critical enzymes in response to oxidative stress. As well as catalase (CAT), GPX1 eliminates hydrogen peroxide (H₂O₂), which is intracellularly generated by oxidative stress or converted from superoxide anions by superoxide dismutase. GPX1 is known to be the principal antioxidant enzyme for oxidative stress because CAT has low affinity for H₂O₂. Therefore, a Se deficiency may exacerbate the pathological conditions associated with diabetes by downregulating the expression of GPX1. Many epidemiological studies demonstrated that serum Se levels were lower in diabetic patients than in healthy individuals. The atrophy and degeneration of pancreatic islets have also been reported in patients with the Se-deficiency syndrome, Keshan disease. Se-insufficient rats were shown to have low serum insulin levels, which were normalized following supplementation with Se. However, recent studies demonstrated that long-term and relatively high dietary supplementation with Se in U.S. adults increased the incidence of type 2 diabetes. Therefore, it is debatable whether supplementation with Se is beneficial for preventing type 2 diabetes.

The objective of this study was to clarify an effective chemical form to supplement Se for the insufficient status and to compare Se bioavailability in pancreas and glucose tolerance with the administration of different selenocompounds: sodium selenite, methylseleninic acid (MSA), and seleno-L-methionine (SeMet), to an ICR mouse model with mild diabetes mellitus, which was developed by impairing insulin secretion with STZ and NA. These mice were fed a Se-deficient diet to prevent the influence of dietary Se sources.

MATERIALS AND METHODS

Selenocompounds and Animals Sodium selenite (99.999% purity), MSA (95%), and SeMet (≥98%) were purchased from Sigma-Aldrich Japan K.K. (Tokyo, Japan). Permission for the animal experiments performed in this study was obtained from the Animal Experiment Room Administration Committee of Setsunan University, and the experiments were conducted according to the Animal Experiment Guidelines of the Faculty of Pharmaceutical Sciences, Setsunan University. Specific pathogen-free male ICR mice (5 weeks old, about 25 g) were purchased from Japan SLC Inc. (Shizuoka, Japan). The animals were maintained at 23±1°C, approximately 40% relative humidity and a light/dark cycle of 12 h each, and had ad libitum access to γ-ray-irradiated pelleted rodent chow (Type NMF, Oriental Yeast Co., Tokyo, Japan) and tap water. The mice were acclimated for 1 week prior to use.

NA/STZ Treatment and Selenocompound Administration The ICR mice (10 mice/group) were fasted for 16 h and then intraperitoneally injected with NA (Sigma-Aldrich) dissolved in saline at a dose of 120 mg/kg body weight. Fifteen minutes after the NA treatment, the mice were intraperitoneally injected with STZ (Sigma-Aldrich) freshly dissolved in 50 mmol/L citrate buffer (pH 4.5) at a dose of 100 mg/kg body weight. After an interval of 1 d, NA and STZ were administered again in the same manner. The next day, animals were orally administered a selenocompound dissolved in saline at a dose of 158 ± 2.3 µg Se (2 µmol/kg body weight/d using a stainless steel gavage needle and a 1 mL-syringe and had ad libitum access to γ-ray-irradiated pelleted rodent chow (Type NMF, Oriental Yeast Co., Tokyo, Japan) and tap water. The mice were acclimated for 1 week prior to use.

Assays of Blood Glucose, Tissue Se, and GPX1

Non-fasting blood glucose levels were measured before and after the treatment with NA/STZ and monitored weekly for 5 weeks. Blood was drawn from the tail vein at 10:00–12:00. The oral glucose tolerance test (OGTT) was performed orally administering glucose at a dose of 2000 mg/kg body weight to overnight-fasted mice 5 weeks after the treatment with NA/STZ. Blood was collected from the tail vein 0, 30, 60, 90, and 120 min after glucose loading. Glucose levels in these blood samples were determined using Glucose Pilot (Aventir Biotech, LLC, West Carlsbad, CA, U.S.A.). After OGTT, the liver and pancreas were then removed and immediately stored in −80°C for storage until assayed. After wet digestion of the tissues (the pancreases of 2 mice were randomly mixed within the same treatment group to increase the quantity) with a mixed acid solution of nitric acid– perchloric acid (2:1, v/v), the Se content was determined by the fluorometric method using 2,3-diaminonaphthalene.

Pancreatic GPX1 activity was determined by the method described by Lawrence and Burk with slight modifications. The pancreas was homogenized with 20 vol. ice-cold 0.2% Triton-X-50 mmol/L phosphate buffer (pH 7.0) and the homogenate was centrifuged at 13000×g for 15 min at 4°C. The supernatant was dialyzed with the 8000 molecular weight (MW)-cut-off membrane against 50 mmol/L phosphate buffer (pH 7.0) to remove glucose metabolites such as methylglyoxal, which can react with H2O2 added as the substrate. The reaction mixture consisted of 50 mmol/L phosphate buffer (pH 7.0), 0.2 mmol/L nicotinamide adenine dinucleotide phosphate (NADPH), 2 mmol/L GSH, 0.2 mmol/L sodium azide, and 1 unit/mL GSH reductase in a total volume of 850 µL. The dialyzed pancreas supernatant (100 µL) was added to the reaction mixture and incubated for 2 min at 25°C before initiating the reaction by the addition of 50 µL 0.3 mmol/L H2O2 solutions. Absorbance at 340 nm was recorded for 1 min and the activity was calculated from the slope of these lines as nanomoles NADPH oxidized per min. Protein was determined by the Bradford method using bovine serum albumin as the protein standard.

standard.

Statistical Analysis  Values in the figures are expressed as the means±S.D. Statistical analysis was carried out by a one-way ANOVA with a Bonferroni correction. The p level was set at 0.05 or 0.01.

RESULTS

Pancreatic Se Bioavailability of Selenocompounds  The effects of administering the different selenocompounds on body weight gain, hepatic and pancreatic Se contents, and pancreatic GPX1 activity in NA/STZ-induced diabetic mice were investigated to compare their Se availabilities. All 3 selenocompounds augmented the mean body weights in NA/STZ-untreated mice (Fig. 1). Body weight gain was suppressed by the NA/STZ treatment. However, body weight was partly restored by the supplementation with SeMet for 5 weeks (Fig. 1C). Both hepatic and pancreatic Se contents significantly increased due to supplementation with the selenocompounds regardless of the NA/STZ treatment, and were the highest with the SeMet administration (Fig. 2). Pancreatic GPX1 activity was significantly enhanced by SeMet, whereas the NA/STZ treatment suppressed its activity (Fig. 3).

Glucose Tolerance by Supplementary Selenocompounds  To investigate the effects of administering the different selenocompounds on glucose tolerance in NA/STZ-induced diabetic mice, non-fasting blood glucose levels before and 1–5 weeks after the NA/STZ treatment as well as glucose levels during OGTT after the 5 weeks were monitored. Supplementation with the selenocompounds had no significant influence on

Fig. 2. Effects of Administering Sodium Selenite (A), MSA (B), and SeMet (C) on Hepatic and Pancreatic Se Contents
The values shown are the mean±S.D. (n=10). Significantly different from the control or NA/STZ treatment group at *p<0.05; **p<0.01.

Fig. 3. Effects of Administering Sodium Selenite (A), MSA (B), and SeMet (C) on Pancreatic GPX1 Activity
The values shown are the mean±S.D. (n=10). Significantly different from the control or NA/STZ treatment group at **p<0.01.
However, selenite and SeMet significantly suppressed the non-fasting blood glucose levels that were increased by the NA/STZ treatment after 3–4 weeks and 4–5 weeks, respectively (Figs. 4A, C). Although blood glucose levels during OGTT increased in NA/STZ-treated mice, only the administration of SeMet significantly lowered glucose levels 90–120 min after glucose loading (Fig. 5).

DISCUSSION

Type 2 diabetes is characterized by hyperglycemia in the context of insulin resistance, which precedes an insulin deficiency by pancreatic β-cell failure as a response to oxidative stress, endoplasmic reticulum stress, and thereby inflammation. STZ is an agent that acts as a nitric oxide donor and is frequently used to induce experimental diabetes in mammals. This chemical specifically produces free radicals in β-cells and causes the fragmentation of DNA chains, which evokes the activation of poly(ADP-ribose)-polymerase and consumption of a large amount of intracellular NAD to repair damaged DNA. The intake of NA has been shown to effectively supplement the consumption of NAD, which ultimately protects β-cells against the disorder induced by the STZ treatment. In our previous study, the induction of experimental diabetes by the NA/STZ-treatment in ICR strain mice was considered to be restricted more than with the STZ treatment alone and was sensitive to hyperglycemia under diabetic conditions. Using the NA/STZ-induced mild diabetic mouse model, the objective of this study was to compare Se bioavail-
ability in pancreas and glucose tolerance with the administration of different selenocompounds: sodium selenite, MSA, and SeMet. Considering the biological availability of Se, it is necessary for Se sources to be metabolized to hydrogen selenide (H$_2$Se), which is a physiologically active form that is incorporated into the selenocysteine residues of selenoenzymes. Selenite can be reduced to H$_2$Se by 2 molecules of GSH and the reductase. MSA can be converted by 4 molecules of GSH to methylselenol, which can be reversibly converted to H$_2$Se. SeMet can be directly converted to methylselenol by cystathionine γ-lyase as well as H$_2$Se through the l-methionine metabolic pathway and seleno-l-cysteine β-lyase.

To avoid the effects of internal Se sources as previously described, mice were fed a Se-deficient diet for 5 weeks in the present study. We then compared the effects of these selenocompounds as agents for H$_2$Se and/or methylselenol metabolic pools on body weight gain, hepatic and pancreatic Se contents, pancreatic GPX1 activity, and blood glucose levels in NA/STZ-induced diabetic mice. The dosage of 158 µg Se (2 µmol)/kg body weight/d was decided as an intake within the physiological range of mouse, which was estimated from Se level in the normal diet and the dietary intake. The administration of the selenocompounds had no detrimental effects on the appearance of the coat, general grooming, or non-fasting glucose levels in NA/STZ-untreated mice. As shown in Fig. 1, the difference observed in mean body weight between the selenocompound-administered and control groups reflected the influence of a Se deficiency. As shown in Figs. 2 and 3, SeMet exhibited the highest bioavailability of the 3 selenocompounds examined, particularly in the pancreatic Se content and GPX1 activity. Only SeMet-supplemented mice exceeded the normal diet-feeding mice in the Se content and GPX1 activity of NA/STZ-untreated groups, as compared with NSY mice that were established as an inbred strain with spontaneous development of diabetes from ICR mice. As cystathionine γ-lyase activity is known to be relatively high in the liver and pancreas, methylselenol may easily be formed from SeMet in these tissues. In our previous study, the activity of GPX4 and TR in the pancreas was negligible. Therefore, GPX1 may be important in the defense system against oxidative stress. As shown in Figs. 4 and 5, SeMet significantly suppressed non-fasting and OGTT glucose levels in NA/STZ-treated mice. However, the administration of MSA had no effect on glucose levels, whereas selenite slightly decreased non-fasting glucose levels. These results suggest that the Se agent for GSH-dependent H$_2$Se or methylselenol metabolic pool shows low Se bioavailability and may not contribute to an improvement in diabetes. Chronic hyperglycemia decreases the expression of pancreatic γ-glutamylcysteine ligase, which is the rate-limiting enzyme for GSH synthesis. A Se deficiency was also shown to decrease the pancreatic GSH content. Selenite and MSA may consume GSH to form H$_2$Se or methylselenol in the pancreas, which has a low Se content. Taken together, a Se agent that has GSH-independent H$_2$Se or a methylselenol metabolic pool may be suitable for the primary prevention of diabetes.

In conclusion, SeMet improved glucose tolerance in the NA/STZ-induced mild diabetic mouse model by exhibiting high bioavailability in the pancreas. In this study, there were no significant differences in non-fasting plasma insulin levels between the control and the selenocompound-administration groups because their levels were very low by NA/STZ treat-ment and close to the detection limit of ELISA assay (data not shown). Further studies will be needed to clarify the protective mechanisms of SeMet from hyperglycemia and an insulin deficiency including assessments of hemoglobin Alc and OGTT plasma insulin.
