Uric acid exerts an important antioxidant effect against external oxidative stress under physiological conditions. However, uric acid itself can increase oxidative stress via reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activation in adipocytes and vascular cells. Uric acid transporter 1 is involved in the generation of this oxidative stress. Furthermore, uric acid locally activates the renin–angiotensin system, thus producing angiotensin II and subsequently increasing intracellular oxidative stress. Benzbromarone has been reported to suppress uric acid reabsorption via uric acid transporter 1 inhibition in renal tubular cells. In this study we evaluated the in vitro antioxidant effect of benzbromarone from several perspectives. First, the direct radical-trapping capability of benzbromarone was measured by chemiluminescence assay and electron paramagnetic resonance spectroscopy. Second, the intracellular antioxidant activity of benzbromarone in hyperuricemia was evaluated using endothelial cells. In light of these results, benzbromarone is hypothesized directly to scavenge the superoxide anion radical. In addition, benzbromarone inhibited reactive oxygen species production that was induced by angiotensin II or uric acid in endothelial cells. These findings suggest that benzbromarone possesses the ability directly to scavenge radicals and may act as an antioxidant against uric acid and angiotensin II-induced oxidative stresses in endothelial cells at therapeutically achievable levels in blood.

Key words benzbromarone; uric acid; reactive oxygen species; endothelial dysfunction

Both the kidneys and the vasculature are rich sources of reactive oxygen species (ROS), particularly superoxide (O2·−), which is mainly generated by reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Excessive ROS derived from NADPH oxidase are involved not only in the pathogenesis of both hypertension and renal disease1–3 but also in the reduction of the potent vasodilator nitric oxide (NO).4–6 In this process, peroxynitrite generated by the reaction between NO and O2·− enhances further oxidation of biological substrates such as proteins, lipids and nucleic acids,7,8 resulting in deteriorating renal dysfunction and vascular damage under pathophysiological conditions.

Uric acid plays an important role in the pathogenesis of ROS-related diseases,9 as it acts at physiological concentrations as a powerful antioxidant that protects endothelial cells from extracellularly generated ROS.10 However, uric acid has been reported to stimulate increases in NADPH oxidase-derived ROS production in adipocytes, vascular smooth muscle cells and vascular endothelial cells.11,12 Furthermore, a recent report suggested that uric acid also activates the local renin–angiotensin system (RAS) and that angiotensin II (AII) increases intracellular oxidative stress by stimulating NADPH oxidase.13 Taken together, these findings provide evidence that uric acid functions as a pro-oxidant in hyperuricemia, despite acting as an antioxidant under physiological conditions. Therefore, the presence of excessive uric acid in the bloodstream such as is seen in hyperuricemia without crystal deposition and gout, is strongly associated with ROS-related disorders, such as cardiovascular disease (CVD), chronic kidney disease (CKD), hypertension and the risk of mortality.14

Benzbromarone is a uricosuric agent that has been used for more than 30 years in clinical practice. Benzobromarone acts by suppressing uric acid reabsorption via inhibition of the uric acid transporter 1 (URAT1) in renal tubular cells, and its maximum blood concentration (Cmax) following 100 mg of oral administration is approximately 2.3 µg/mL (5.4 µM) in healthy subjects.15 Both benzbromarone and probenecid, a URAT1 inhibitor, have previously been reported to inhibit intracellular NADPH oxidase-derived ROS production by interfering with uric acid uptake via URAT1 in adipocytes and vascular smooth muscle cells.11,16 Moreover, benzbromarone, in contrast to probenecid, has a phenolic hydroxy group that may be involved in its radical trapping action. Therefore, we speculate that benzbromarone may possess an additional mechanism of ROS inhibition, particularly direct ROS scavenging, along with a decrease of NADPH oxidase-derived ROS production via URAT1 inhibition. Thus, we first examined the direct radical-trapping capacity of benzbromarone using a chemilu-
minescence assay and electron paramagnetic resonance (EPR) spectroscopy. Subsequently, the antioxidant activity of therapeutic concentrations of benzbrmorarone in hyperuricemia or under RAS activation was evaluated in human umbilical vein endothelial cells (HUVECs).

MATERIALS AND METHODS

Chemicals and Materials Xanthine (X), Xanthine oxidase (XO), uric acid sodium salt, 2-amino-4-hydroxypteridine (pterin), 2-amino-4,7-dihydroxypteridine (isoxanthopterin), 2-butyln hydroperoxide (t-Bu), Cu, Zn-superoxide dismutase (Cu, Zn-SOD), AIJ, Benzbrmorarone and allopurinol (ALP) were purchased from Sigma Chemical Co. (St. Louis, MO, U.S.A.). 2,2-Dimethyl-3,4-dihydro-2H-pyrrole-1-oxide (DMPO) was purchased from Alexis Corporation. 5-(and-6)-Chloromethyl-2,2-dimethyl-3,4-dihydro-2H-pyrrole-1-oxide (DMPO) was purchased from CalBiochem Inc. (San Diego, CA, U.S.A.). 5-(and-6)-Chloromethyl-2,2-dimethyl-3,4-dihydro-2H-pyrrole-1-oxide (DMPO) was purchased from Alexis Corporation. 5-(and-6)-Chloromethyl-2,2-dimethyl-3,4-dihydro-2H-pyrrole-1-oxide (DMPO) was purchased from CalBiochem Inc. (San Diego, CA, U.S.A.).

Chemiluminescence Assay The chemiluminescence response to O₂⁻ or the peroxyl radical (LOO⁻) generated by the X/XO or Hb/t-Bu system was continuously measured and recorded for 10 min at room temperature using a luminometer (MiniLumat LB 9506, Berthold Technologies, TN, U.S.A.). The reaction of the X/XO system was initiated by adding 40 µg/mL X to phosphate buffered saline (PBS; pH 7.4) containing 0.004 U/mL XO, 250 µM DTPA and 500 µM luminal in the absence or presence of benzbrmorarone. Cu, Zn-SOD (5 U/mL) was added to the above mixture to confirm the specificity of the reaction. The reaction of the Hb/t-Bu system was initiated by adding 0.1 µM t-Bu to the PBS containing 4 µg/mL Hb, and 500 µM luminal in the absence or presence of benzbrmorarone. To confirm the specificity of the reaction, 100 µM Trolox was used as a positive control and was added to the above mixture. The activity of XO was determined by monitoring the conversion of X to uric acid, according to a previous report.17) ALP was used to confirm the positive reaction.

EPR Spectroscopy Superoxide concentrations from human neutrophils were determined using EPR spin trapping with EMPO, and the scavenging activity was calculated from the relative peak intensities corresponding to the EMPO-superoxide adduct (EMPO-OOH) EPR signal. Human neutrophils (1.0×10⁶ cells/mL) were pre-treated with phorbol myristate acetate (10 ng/mL) for 7 min at 37°C to activate the cells. Aliquots of this cell suspension were combined with 100 µM DTPA and 25 mM EMPO in Hank’s Balanced Salt Solution (HBSS) in the absence or presence of varying benzbrmorarone concentrations and were immediately transferred to quartz EPR flat cells. EPR spectra were recorded at room temperature on an EPR spectrometer (JES-TE 200, JEOL Ltd., Tokyo, Japan) under the following conditions: modulation frequency, 100 kHz; modulation amplitude, 50 Gauss; scanning field, 335±2.5 mT; receiver gain, 300–500; response time, 0.03 s; sweep time, 2 min; microwave power, 40 mW; and microwave frequency, 9.43 GHz. Cu, Zn-SOD (5 µ/mL) was used as a positive control and was added to the above mixture to confirm the reaction. After recording the EPR spectra, the signal intensities of the EMPO-OOH adducts were normalized against that of a manganese oxide (Mn⁷⁺) signal, in which Mn⁷⁺ served as an internal control.

Cell Culture HUVECs were cultured in MCDB131 medium containing 5% FCS under standard cell culture conditions (humidified atmosphere, 5% CO₂, 37°C). HUVECs were seeded to collagen-coated tissue culture flasks and further grown to confluence until used in cellular assays. HUVECs were used in experiments at passages between 3 and 5.

Measurement of ROS Production To measure the production of ROS, CM-H₂DCFDA, a ROS-sensitive fluorescent dye, was used as a ROS probe. HUVECs were cultured in 96-well plates (8×10⁴ cells/well) at 37°C for 24 h, and then incubated with HBSS containing 5 µM CM-H₂DCFDA for 30 min to incorporate CM-H₂DCFDA into the cells. After removal of HBSS and rinsing CM-H₂DCFDA from the cells, the cells were incubated with benzbrmorarone (1.2–23.4 µM) in medium for 30 min and then added to 50 µM AII or 536 µM (0.9 mg/dL) uric acid. Mean fluorescence intensity (MFI) was measured as intracellular ROS production (excitation 485 nm and emission 535 nm) after 1 h using a fluorescence microplate reader (SPECTRA FLUOR, TECAN Ltd., Männedorf, Switzerland). NAC was used as a positive control.

Viability of HUVECs HUVECs were incubated in 96-well plates (8×10⁴ cells/mL) at 37°C for 24 h. The culture medium was then removed and washed twice with HBSS. HUVECs were added to benzbrmorarone, and then incubated with uric acid for 24 h. Cell viability was determined after 24 h post treatment growth in 96-well culture plates with the Cell Counting Kit-8 (Dojindo Laboratories, Kumamoto, Japan) assays according to the manufacturer’s instructions. NAC was used as a positive control.

Statistical Analysis The results are reported as the mean±S.D. Among 2 > mean values, statistical significance was evaluated by Tukey−Kramer. Bonferroni’s test was used for EPR data. For all analyses, p<0.05 was regarded as being statistically significant.

RESULTS

Benzbrmorarone Scavenges O₂⁻ and LOO⁻ Using Chemiluminescence Assay The antioxidant activity of benzbrmorarone against O₂⁻ generated by the X/XO system was examined using chemiluminescence assay. As shown in Fig. 1A, benzbrmorarone decreased the chemiluminescence responses to O₂⁻ at concentrations of 1.2–23.4 µM. In addition, the amount of uric acid, the metabolite of X in this system, was not affected by benzbrmorarone, indicating that benzbrmorarone, unlike the XO inhibitor allopurinol, has no effect on XO activity (Fig. 1B). Similar experiments were also performed using the Hb/t-Bu system, which mainly generated LOO⁻. As a result, chemiluminescence response with LOO⁻ was also decreased by benzbrmorarone (Fig. 1C).

Benzbrmorarone Scavenges O₂⁻ Derived from Polymorphonuclear Neutrophils Using EPR Spectroscopy
scavenging activity of benzbromarone against $O_2^-$ was also examined in a cell system. Benzbromarone scavenged $O_2^-$ derived from phorbol myristate acetate-stimulated human neutrophils (Figs. 2A, B). Moreover, benzbromarone exerted radical scavenging activity at a lower concentration than $C_{\text{max}}$ (5.4 µM).

**Effect of Benzbromarone on Intracellular Uric Acid-Induced ROS Production and Cell Viability in HUVECs**

Next, the intracellular antioxidant activity of benzbromarone in hyperuricemia was evaluated using human endothelial cells. Uric acid induced oxidative stress at 536 µM, and benzbromarone significantly inhibited uric acid-induced intracellular ROS production under pathophysiological conditions in HUVECs (Fig. 3A). In association with ROS production, the decreased viability of HUVECs by uric acid treatment (536 µM) was improved by incubation with benzbromarone (Fig. 3B).

**Effect of Benzbromarone on AII-Induced Intracellular ROS Production in HUVECs**

As described in the introduction, uric acid activates the local RAS, leading to the production of AII. Therefore, we examined the effect of benzbromarone on the intracellular ROS production stimulated by AII in HUVECs. When AII was added to HUVECs, a significant increase in the fluorescence intensity was observed. However, the fluorescence intensity was decreased by the co-treatment of benzbromarone at concentrations approximately equal to $C_{\text{max}}$ (Fig. 4).

**DISCUSSION**

When uric acid is taken up by adipocytes, $O_2^-$ synthesis is catalyzed by NADPH oxidase and lipid radicals. Furthermore, excessive AII production, as a result of RAS activation by uric acid, leads to collapse of the intracellular redox state and cause the induction of apoptosis and growth inhibition of the endothelial cells. In the present study, we first revealed that benzbromarone, an antihyperuricemic drug, possesses direct scavenging ability against $O_2^-$ and LOO$^-$ within clini-

cally therapeutic concentrations. In addition, benzbromarone suppressed ROS production induced by uric acid and AII in vascular endothelial cells. The direct and indirect antioxidant activities of benzbromarone are thought to exert a protective effect on cells and tissues against ROS-derived damage. It is well known that $O_2^-$ is key in initiating the production of various ROS, such as hydroxyl radicals and peroxynitrite, under physiological conditions. In addition, $O_2^-$ mediates pro-oxidative and proinflammatory changes in endothelial cells. This $O_2^-$-induced damage can disrupt the balance between vasodilation and vasoconstriction, which affects arterial remodeling and inflammatory mediators. Therefore, oxidative stress derived from $O_2^-$ may cause cumulative injuries to the endothelium and consequently, may be involved in the pathogenesis of cardiovascular disease, hypertension and kidney disease.20,21 Our study clearly showed that benzbromarone is a potent scavenger of $O_2^-$ generated from both the X/O system (Fig. 1A) and activated neutrophils (Fig. 2). Furthermore, benzbromarone prevented cell death related to intracellular ROS production (Fig. 3). Hyperuricemia is strongly associated with CVD and CKD and the increased risk of mortality.22 Benzbromarone may exert a stabilizing effect on CKD and CVD. In fact, a retrospective study reported that patients with renal impairment (CKD stage 3 or higher) receiving benzbromarone monotherapy did not observe a further deterioration in renal function.20

As described above, benzbromarone directly scavenges ROS, such as $O_2^-$ and LOO·, at clinical concentrations (Figs. 1, 2). Therefore, the mechanism of ROS suppression could be explained in part by the direct interaction of benzbromarone with $O_2^-$, R20. Recently, Anzai and Endou reported that IC50 for benzbromarone against URAT1 was 0.05 µM.21 In addition, it was reported that benzbromarone partially inhibited voltage-driven urate transporter 1 (URAT1), the extracellular uric acid efflux transporter, in the renal tubular cell.22 Considering these reports and our data that 1.2 µM of benzbromarone inhibited ROS by approximately 10%, benzbromarone might affect both URAT1 and URAT1v. Further studies are necessary to clarify the antioxidant pathway of benzbromarone in greater detail.

Recently, uric acid has been reported to induce a substan-
tial oxidative burst at physiological concentrations (357 µM or more), which was associated with local RAS activation, AII production and the induction of senescence and apoptosis of human endothelial cells.23 Indeed, both hyperuricemic and AII-infused rats developed hypertension, afferent arteriopathy, glomerular hypertrophy and interstitial inflammation in the kidney.24–26 In this study using HUVECs, for the first time, we have demonstrated the protective effects of benzbromarone against AII-derived ROS (Fig. 4). Furthermore, a good correlation was observed between cell viability and oxidative stress ($r=0.937, p<0.01$, data not shown). Therefore, the antioxidant activity of benzbromarone is thought to be responsible for its cytoprotective effects. Benzbromarone reduces ROS generated by local activation of the RAS in hyperuricemia and may be a useful uricosuric agent against cardiovascular disease and hypertension.

In Japan and a number of other countries, benzbromarone and allopurinol are widely used for the treatment of hyperuricemia. Allopurinol inhibits ROS production by working as an XO inhibitor but not as a radical scavenger,27 whereas benzbromarone decreases ROS production directly and indirectly by working as both a URAT1 inhibitor and radical scavenger, respectively. Moreover, although oxypurinol, the active metabolite of allopurinol, causes severe side effects such as toxic epidermal necrosis or agranulocytosis in hyperuricemic patients with renal failure,28,29 benzbromarone was reported to increase the renal clearance of oxypurinol via URAT1 inhibition in the renal tubular reabsorption of oxypurinol.29 Therefore, the combination of benzbromarone with allopurinol is useful for achieving better therapeutic effects in treating hyperuricemia and associated diseases such as CVD or CKD due to its effective oxidative stress-reducing ability and by alleviating the side effects of oxypurinol.
