Received February 26, 1996; accepted April 22, 1996

The relationship between the plasma drug concentration and the antihypertensive effect of felodipine was analyzed by an ion-channel binding model which takes into consideration the slow association/dissociation process of a drug at the calcium channel. The in vitro dissociation constant (Ka) of felodipine to the calcium channel in the heart of rats was determined, and was compared to the in vivo dissociation constant (Kd,app) estimated by the pharmacodynamic analysis of the concentration–effect data in Japanese essential hypertensive patients obtained from literature. The relative relationship between Kd and Kd,app of felodipine was substantially identical with eight other calcium channel blocking agents reported previously. This result suggested the possibility that we can predict the pharmacodynamic behavior of newly developed calcium channel blocking agents from the in vitro Ka value and plasma concentration–time profile in human using the ion-channel binding model.

Key words felodipine; calcium channel blocker; pharmacodynamic model

It is well known that several long-acting calcium channel antagonists rapidly disappear from plasma in comparison to the duration of their pharmacological effects. In our previous study, the relationship between the plasma concentration and the antihypertensive effect of eight calcium channel antagonists was analyzed by the effect compartment model and the newly developed ion-channel binding model.1) The latter includes the slow association/dissociation rate of drugs to the calcium channel, and the dissociation constants estimated from in vivo pharmacodynamic analysis were well correlated to the dissociation constants measured by in vitro binding inhibition study, suggesting that the long-acting property of these drugs is due to their high affinity to the calcium channel and slow dissociation rate. Based on the developed ion-channel binding model, we may be able to predict the pharmacological behavior of long-acting calcium antagonists from the dissociation constant measured by in vitro binding studies and the pharmacokinetic data obtained from clinical study. To evaluate the validity of this assumption, it is useful to apply the ion-channel binding model to other calcium channel blocking agents. In this study, we determined the inhibition constant of felodipine to the specific binding of [3H]nitrendipine to the calcium channel in the heart of rats, and compared our results to the pharmacodynamically estimated Ka value to evaluate the validity of ion-channel binding model analysis.

MATERIALS AND METHODS

Chemicals and Reagents [3H]Nitrendipine (73.5 Ci/mmol) was obtained from Amersham-Japan (Tokyo, Japan). Nifedipine, nitrendipine and felodipine were kindly provided by Bayer AG (Japan), Yoshitomi Pharmaceutical Industries, Ltd. (Japan) and Hoechst Japan, Ltd. (Japan), respectively. All other compounds were of analytical grade and were purchased from Wako Pure Chemical Industries.

Calcium Channel Blocking Activity Male Wistar rats (300–360 g) were killed by exsanguination under ether anesthesia. The hearts were taken and homogenized in a Polytron homogenizer with 20 volumes of ice-cold 50 mm Tris–HCl buffer (pH 7.5) and centrifuged at 500 × g for 10 min at 4°C. The supernatant was centrifuged at 35000 × g for 10 min at 4°C. The pellet was suspended in the initial volume of Tris–HCl buffer. This washing step was repeated twice. The final pellet was resuspended and homogenized in 25 volumes of 50 mm Tris–HCl buffer in a Teflon homogenizer. One milliliter of this homogenate was used in the binding assay.

[3H]Nitrendipine, nitrendipine, nifedipine and felodipine were dissolved in 10% methanol. To polystyrene tubes containing 50 μl of [3H]nitrendipine (6.6 nM) and 50 μl of the various concentrations of nitrendipine or felodipine, 1 ml of heart membrane homogenate was added. Nonspecific binding was determined in the presence of 1 μM nifedipine. The mixture was incubated for 90 min at 25°C. The mixture was filtered under reduced pressure in a Sampling Manifold (Millipore, Japan) through GF/C glass fiber filters (Whatman, Inc., Maidstone, England). Each filter was washed four times with 5 ml of ice-cold Tris–HCl buffer. Eight milliliters of scintillator (Scintisol EX-H, Wako Pure Chemical Industries, Ltd., Japan) were added to the filter and the radioactivity was measured by a liquid scintillation counter. The assay procedure was always carried out in duplicate.

The calcium channel blocking activity of nitrendipine was estimated by Eq. 1.

\[
C_50 = \left( \frac{n_{app,1} \cdot C_I + n_{app,2} \cdot C_I}{K_{a,1} + C_I} \right) + \left( \frac{n_{app,1} \cdot C_I + n_{app,2} \cdot C_I}{K_{a,2} + C_I} \right)
\]

where \( n_{app,1} \) and \( K_{a,1} \) represent the number of binding sites and the dissociation constant for the high-affinity site, respectively, and \( n_{app,2} \) and \( K_{a,2} \) are those for the low-affinity site \( (K_{d,1} < K_{a,2}) \) connecting the free drug concentration (\( C_I \)) to the binding drug concentration (\( C_b \)).

The IC50 value of felodipine under the condition of a low concentration of nitrendipine (high-affinity site) was

© 1996 Pharmaceutical Society of Japan
estimated by fitting Eq. 2 to the data:
\[ B_{\text{rel}} = I_{C_{50}}(1+C_{\text{rel}}) \]  
(2)

where \( B_{\text{rel}} \) and \( C_{\text{rel}} \) are the binding ratio of \(^3\text{H}\)-nitrendipine and the concentration of felodipine used in the binding assay, respectively. The inhibitory constant (\( K_i \)) of felodipine was calculated as follows:
\[ K_i = I_{C_{50}}(1+[L^*]/K_{a,i}) \]  
(3)

where \([L^*]\) is the concentration of \(^3\text{H}\)nitrendipine.

**Pharmacodynamic Analysis Based on the Ion-Channel Binding Model**

Pharmacokinetic and pharmacodynamic data after the single oral administration of felodipine (5 mg) in Japanese essential hypertensive patients (classification of WHO, stage I, stage II, and stage III, except the patients who had grave infirmity) were obtained from the literature. The ages of the patients were from thirty-one to sixty-five, three males and eight females. The monitoring of the antihypertensive effect of felodipine started at eight a.m. The antihypertensive effect was expressed as the change in systolic blood pressure (mmHg) from the initial blood pressure before drug administration.

A pharmacodynamic model for the antihypertensive effect of calcium channel blocking agents was described in a previous study. A linear three-compartment model with first order absorption was selected as the model equation with the minimum Akaike's information criterion and was fitted to the plasma concentration curve of felodipine using the nonlinear least squares regression method.
\[ C_p = (-A + B + C) \cdot \exp(-k_{a} \cdot t) + A \cdot \exp(-\alpha \cdot t) \]
\[ + B \cdot \exp(-\beta \cdot t) + C \cdot \exp(-\gamma \cdot t) \]  
(4)

where \( C_p \) is the plasma concentration, and \( A, B, C, \alpha, \beta, \gamma \) and \( k_a \) are hybrid pharmacokinetic parameters. In the ion-channel binding model, we assumed that the drug in plasma directly acted on the calcium channel at the target site with the second order association constant (\( K_{a} \)) and the first order dissociation rate constant (\( k_{a} \)). The differential equations for pharmacodynamic analysis are as follows:
\[ \frac{d[R]}{dt} = -k_{a} \cdot [C_p] \cdot [R] - k_{off} \cdot [RC] \]  
(5)
\[ \frac{d[RC]}{dt} = -k_{on} \cdot [C_p] \cdot [R] - k_{off} \cdot [RC] \]  
(6)

where \([R]\) and \([RC]\) are the concentrations of the free calcium channel and the calcium channel blocked by the drug, respectively. The total calcium channel concentration \([R]\) is the sum of \([R]\) and \([RC]\) as follows:
\[ [R] + [RC] = [R] \]  
(7)

Rearranging Eq. 5 and Eq. 7 yields Eq. 8.
\[ \frac{d[RC]}{dt} = k_{on} \cdot [C_p] \cdot ([R] - [RC]) - k_{off} \cdot [RC] \]  
(8)

Assuming that the pharmacological effect \( E \) is proportional to \([RC]\) and that the maximum effect \( E_{\text{max}} \) is obtained when \([RC] = [R]\), the relationship between \( C_p \) and the pharmacological effect \( E \) (mmHg) is as follows:
\[ \frac{dE}{dt} = k_{on} \cdot [C_p] \cdot (E_{\text{max}} - E) - k_{off} \cdot E \]  
(9)

Equations 4 and 9 were fitted to the mean time course for antihypertensive response to estimate \( E_{\text{max}} \), \( k_{on} \) and \( k_{off} \) for the ion-channel binding model using a nonlinear least squares method.

Further, an apparent in vivo dissociation constant, \( K_{d, \text{calc}} \), was calculated according to the following equation:
\[ K_{d, \text{calc}} = k_{off} / k_{on} \]  
(10)

**RESULTS AND DISCUSSION**

Figure 1 shows a typical Scatchard plot of nitrendipine. It was suggested that there were two binding sites of nitrendipine on the calcium channel. The dissociation constant of nitrendipine to the high-affinity site was 0.36 nm, which was similar to that determined by other investigators. The inhibitive activity of felodipine to the binding of nitrendipine was determined as shown in Fig. 2. The inhibitory constant (\( K_i \)) of felodipine estimated by Eq. 3 was 0.29 nm. The activity was higher than the other calcium channel blocking agents, nitrendipine, nifedipine, barnidipine, nilvadipine, and nicardipine.

![Fig. 1. The Typical Scatchard Plot of Nitrendipine](image1)

The solid line is the fitted curve to the experimental data. The dissociation constant of nitrendipine to the high-affinity site was 0.36 ± 0.069 (mean ± S.E.) nm, and \( K_{d, \text{calc}} \) was 88.1 ± 14.3 (mean ± S.E.) μmol/mg protein. The dissociation constant to the low-affinity site was 53.6 ± 24.3 (mean ± S.E.) nm, and \( K_{d, \text{calc}} \) was 2.54 ± 0.81 (mean ± S.E.) μmol/mg protein.

Each symbol represents the mean of eleven patients reported previously. Solid line indicates the fitted line according to an ion-channel binding model. The inset is the plasma concentration profile of felodipine and the fitted curve used by the linear three-compartment model.

Fig. 4. Relationship between in Vitro $K_d$ Values and the in Vitro $K_{d,calc}$ Values Estimated by an Ion-Channel Binding Model Analysis

All data except for felodipine were analyzed in the previous study. •, felodipine; ○, nicardipine; ▽, nifedipine; ◊, nilvadipine; ▲, benidipine; △, manidipine; ▲, barnidipine; ◊, nitrendipine; •, ofonidipine.

However, the affinity of calcium channel blocking agents to the calcium channel are known to have tissue specificity and interspecies differences, therefore, comparison of the affinity of various calcium channel blocking agents by in vitro study may be required using the same tissue of the same animal to compare the intrinsic potency of these drugs.

Figure 3 shows the observed antihypertensive effects of felodipine and the fitted lines based on the ion-channel binding model. The fitted curve of felodipine was coincident with the observed data. Therefore, the delays and duration in pharmacological effect of calcium antagonists could be explained by the ion-channel binding model as other calcium channel blocking agents. The estimated pharmacodynamic parameters, $E_{max}$, $k_{on}$, $k_{off}$ and $K_{d,calc}$ are $28.6 \pm 5.2$ mmHg, $0.156 \pm 0.048$ nm$^{-1}$ h$^{-1}$, $0.160 \pm 0.074$ h$^{-1}$ (optimal estimate ± S.D.) and 0.98 nm, respectively.

The relative relationship between the $K_d$ value ($K_v$ value estimated by Eq. 3), measured by in vitro study, and $K_{d,calc}$ estimated from in vivo pharmacodynamic analysis, was consistent with those of eight other calcium channel blocking agents obtained previously (Fig. 4). This result suggested that we can predict the pharmacodynamic behavior of calcium channel blocking agents from their pharmacokinetic properties and the dissociation rate from the calcium channel. Estimation of the $K_d$ value is very important for the prediction of the pharmacodynamic property of long-acting calcium channel blocking agents such as benidipine, manidipine and felodipine, since their dissociation rates from the calcium channel were much slower compared with their elimination rate from plasma.

The ion-channel binding model does not consider the effect of plasma/serum protein binding. The dihydropyridine calcium channel blocking agents extensively bind to plasma proteins, and their unbound form may be directly related to their pharmacological effect. Further, it is said that the calcium channel protein is embedded within the lipid membrane bilayer, and the concentration in the lipid membrane may be more important. Therefore, in order to improve the predictability of a pharmacodynamic property, investigation into the unbound concentration in plasma and the partition to the lipid membrane is required in the future.

In conclusion, ion-channel binding model analysis may be applicable to most calcium channel blocking agents, of which the dissociation rate from the calcium channel are slow, and it is important to estimate the $K_d$ value to predict the pharmacodynamic properties of these drugs. Since the relative relationship between $K_d$ and $K_{d,calc}$ of felodipine was substantially identical with other calcium channel blocking agents, we can evaluate the pharmacodynamic behavior of felodipine from the $K_d$ value and pharmacokinetic properties of this drug.
