Increasing Mortality From Pulmonary Embolism in Japan, 1951–2000

Masahito Sakuma, MD; Yuji Konno, MD; Kunio Shirato, MD

In the United States, annual mortality rates from pulmonary embolism (PE) tended to increase from the 1960s to the mid 1980s, but thereafter began to decrease. In Japan, PE is not yet widespread and there have not been any reports of the time-trend of its mortality rate. The present study calculated the annual age-adjusted and age-specific PE mortality rates for Japanese residents during 1951 to 2000 from the ‘Vital Statistics of Japan’ and the census data and population estimates for the intercensal years. Throughout the study period, the age-adjusted deaths and mortality rates from PE continued to increase, and between 1976 and 1996 the increases in the annual age-specific mortality rates were substantial in males 45–49 years of age and 55 years or older, and in females 30 years of age or older. The age-specific PE death rates increased throughout the life span in general and according to the decade. Male mortality was greater at most ages. In Poisson regression analysis, the relative risk of death from PE was increased in males, the aged, and in recent years. Overall, mortality from PE in Japan increased significantly during 1951 to 2000. (Circ J 2002; 66: 1144–1149)

Key Words: Cardiovascular disease; Mortality; Pulmonary circulation; Pulmonary embolism

Pulmonary embolism (PE) has not yet become widespread in Japan. The number of patients with PE per year is estimated at more than 600,000 in the United States1 whereas in 1996 in Japan there were only approximately 3,500 cases2 In the US, annual mortality rates from PE tended to increase from the 1960s to the mid 1980s3 but thereafter began to decrease4 In Japan, routine autopsy examinations have revealed that the deaths from PE have been increasing5–7 but there has not been a report of the time-trend of the mortality rate of PE. The present study examined the annual change in the mortality rate and compared the Japanese data with those from the US.

Methods

Data on deaths and population for the period 1951–2000 were obtained from the ‘Vital statistics of Japan’8–10 census data11 and population estimates for the intercensal years10 The register is based on death certificates issued by doctors. These data were reviewed for deaths in which PE was coded as the underlining cause (for 1951–67 ICD-7, rubric 465; for 1968–78 ICD-8, rubric 450; for 1979–94 ICD-9 rubric 415.1; for 1995–2000 ICD-10, rubric I26). The annual age-adjusted PE deaths; that is: ln (age-adjusted deaths) = ln (decaths) + ln (population size) + ln (10-year age group). The reference categories were male, the 1951–60 period and the under 20 years age group. These results were summarized by presenting the relative risk of PE.

Results

The age-adjusted deaths and mortality rates from PE are tabulated in 10-year steps from 1956 to 1996 in Table 1 and and the population of 80 or older as the population data in those years. Moreover, the number of PE patients (ICD-9 rubric 415.1) was reported separately from that of other acute pulmonary heart diseases (ICD-9 rubric 415.0) in total, but not by age during 1979 to 1994. In order of years from 1979 to 1994, the number of other acute pulmonary heart diseases in males was 8, 2, 0, 5, 6, 6, 1, 3, 1, 3, 2, 1, 3, 4, 3 and 3, respectively; and in females, 3, 5, 7, 3, 2, 0, 1, 3, 0, 1, 0, 1, 1, 1, 2 and 2. Therefore, the annual age-adjusted deaths and mortality rates from PE included those from other acute pulmonary heart diseases in those years.

The annual age-specific mortality rates in Japan by gender were generated using the same resources8–10 and the percentage changes from 1979 to 1996 in the age-gender-specific rates were calculated. The data in those years were selected for comparison with the data in the report by Lilienfeld4 who examined the mortality from PE in the United States.

The percent changes from 1979 to 1996 in the age-gender-specific rates were analyzed using the standard z-test11 For 2 Poisson regression analyses12 we used the GENMOD procedure (generalized linear models) in SAS for Windows version 6.12 (SAS Institute, Cary, NC, USA). One was fitted for the calendar year on age-adjusted PE deaths; that is: ln (age-adjusted deaths) = ln (component year) + ln (calendar year), where the calendar year was given as 1, 2, ..., 50 (year 1 is 1951, year 2 is 1952, and so on to 2000). Another Poisson regression was fitted for each gender, calendar year and 5-year age group on PE mortality; that is: ln (deaths) = ln (population size) + ln (gender) + ln (calendar year in decade) + ln (10-year age group). The reference categories were male, the 1951–60 period and the under 20 years age group. These results were summarized by presenting the relative risk of PE.
Mortality From PE in Japan

Circulation Journal Vol.66, December 2002

it can be seen that they continue to increase in Japan (Fig 1).

The annual age-adjusted PE mortality rates markedly
increased in both genders in every decade and in the 1980s,
women exceeded men in age-adjusted deaths and mortality
rates. The age-adjusted mortality rates in Japan during
1951 to 2000 are shown in Fig 2, together with the fitting
curve, the slope of which ($\beta$) was positive and statistically
significant at the 0.0001 level.

The changes in the annual age-specific PE mortality
rates in Japan between 1979 and 1996 by gender are shown
in Table 2 and it can be seen that the increases in the rates
were substantial in males 45–49 years old and in those 55
years or older, as they were in females 20–24 years old and
in those 30 years or older. The age-specific PE death rates
in Japan in 5 decades are shown in Fig 3; generally, the
rates increased throughout the life span and according to
the decade, but male mortality was greater than that of

females at most ages.

In Poisson regression analysis, the relative risk of PE mortality was elevated in males, the aged, and in recent years (Table 3).

### Discussion

There are various reasons why the age-adjusted mortality rates from PE are rapidly increasing in Japan. First is the improvement in correct diagnosis of the disease, which has also been described as a cause of the increment in the mortality rates from PE in the United States from the 1960s to the mid 1980s. The clinically diagnosed rate in autopsy examinations ranged from 28.7% in 1987 to 45.3% in 1997 in Japan, which supports this hypothesis.

Second is the Westernization of life style in Japan, including diet. Based on the national nutrition survey in Japan, energy intake from both fish and meat, lipids and vegetables has been increasing, but that from cereal and the consumption of fish compared with meat has been decreasing. Physically, the body mass index has increased in recent years. Moreover, the number of patients suffering from hyperlipidemia has increased and some reports have described hyperlipidemia as a risk factor for venous thromboembolism. de Lorgeril et al. indicated that PE after myocardial infarction occurred in 2/219 of patients with a Mediterranean-type diet, but in 3/204 patients with a prudent Western-type diet. However, it remains to be determined how much these changes in life style influence the occurrence of PE.

The age-specific mortality rate from PE is increasing year by year in Japan (Fig 3) and moreover, the frequency has been increasing with age. Furthermore, in the Poisson regression analysis showed that the relative risk of PE mortality is elevated in males, the aged, and in recent years. An age-dependent elevation in the mortality rate has been seen in Western countries and resembles the clinical data in Japan described by Kumasaka et al. and Nakamura et al.

In Japan, the increment of cases with PE is clear not only in the mortality rate shown in the present study, but also in autopsy examinations and clinical studies. In clinical examinations, the number of cases with PE increased from 3,492 (95% confidence interval: 3,280–3,703) in 1996 to 4,020 (95% CI: 3,704–4,305) in 2000.

As shown in Table 2, the mortality rate from PE increased particularly in elderly persons in Japan when comparing the data from 1979 with those of 1996. In contrast, Lilienfeld showed that in the US the mortality rate declined among all ages and race groups during the same period. The risk factors for PE in Japan are similar to those in Western countries, but high-risk patients commonly receive prophylaxis in the West, which is less usual in Japan where there are no guidelines for prophylaxis for PE and each doctor must make the decision for individual cases. Differences in the use of prophylaxis for PE between Japan and Western countries may have influenced the trend of the mortality rate.

Age-adjusted mortality rates and age-specific mortality rates in 1996 were similar between Japanese in our study and non-black non-white Americans reported by Lilienfeld. The similarity was only a transient result of the accelerated elevation of mortality rates in Japan and the decline of mortality rates in the US. This comparison and the data on the number of clinical cases in Japan and the United States make the problem of the clinical diagnosis rate in Japan obvious, although a direct comparison with the age-adjusted mortality rates in the US cannot be accepted strictly because the standardized populations differ between the 2 countries.

The mortality rates from PE in Japan are increasing, but are still lower than in Western countries. Lilienfeld and Klatsky et al. reported that mortality rates from PE were less frequent in non-black non-white than in black or white subjects and it appears that PE is not so usual in Mongoloid compared with Caucasian or black people. There are some differences in the hereditary risks for PE; for example, factor V Leiden and Prothrombin G20210A mutation, which are common in Western countries, have not been reported yet in the Japanese population.

The age-adjusted mortality rates from PE in females exceeded those in males in Japan in the 1980s, but the age-specific mortality rates in males are still higher than in females. The ratio of individuals 60 (70) years or older in 1996 exceeded those in males in Japan in the 1980s, but the age-specific mortality rates were similar to those of non-black non-whites in the United States, resulting from the incremental trend of age-adjusted mortality rates in Japan and the decremental rates in the United States.

### Conclusions

To date, there have been no reports on the trend of age-adjusted and age-specific mortality rates from PE in Japan and the results of the present study and their comparison with data from US studies were revealing. Age-adjusted mortality rates from PE are increasing and in females exceeded those of males in the 1980s. The relative risk of PE mortality is elevated in males, the aged, and in recent years. In 1996, the age-adjusted mortality rates in Japan were similar to those of non-black non-whites in the United States, resulting from the incremental trend of age-adjusted mortality rates in Japan and the decremental rates in the United States.
