Background  There have been a number of recent reports on the use of autologous bone marrow implantation (BMI) in the treatment of peripheral arterial disease, with a clinical response rate of approximately 70%. However, the factors that influence efficacy have not yet been clarified. We have analyzed the relationship between the number of implanted bone marrow cells and the clinical efficacy of BMI.

Methods and Results  Eight patients with arteriosclerosis obliterans were treated with BMI. Bone marrow was aspirated from the ilium (500–1,000 ml), the mononuclear cells were separated and then were implanted. The clinical effectiveness of BMI was evaluated by assessing changes in the ankle-brachial pressure index (ABI) and the transcutaneous oxygen pressure (TcO2) between the pre-treatment baseline, with follow-up testing at 4 weeks. These changes were defined as ΔABI and ΔTcO2. The mean number of CD34-positive cells was $1.04\pm0.60\times10^6$ /kg body weight. There was a strong correlation between the number of CD34-positive cells and ΔABI ($r=0.754, p=0.028$).

Conclusions  It is likely that the number of implanted CD34-positive cells is one of the primary factors that influence the clinical efficacy of BMI.  (Circ J 2004; 68: 1189–1193)

Key Words:  Angiogenesis; Arteriosclerosis obliterans; Bone marrow implantation; CD34-positive cells; Mononuclear cells

In adults, the neovascularization that has been observed in injured tissue, cancer and in the endometrium has been thought to be due to angiogenesis, that is those new vessels arise from existing vessels in the tissue through budding and elongation. Asahara et al have recently shown that endothelial progenitor cells (EPC) are regularly found circulating in adult human blood and that these cells have a role in neovascularization through the process of “vasculogenesis”1 Bone marrow-derived smooth muscle cell-like cells were recently reported and a new concept of common vascular progenitors has been proposed that differentiates vascular endothelial cells and smooth muscle cells2 The rate of vasculogenesis in new vessels in an animal model was estimated to be about 10%3 In this model, EPC that had been harvested from bone marrow were injected into an ischemic limb in order to augment angiogenesis and vasculogenesis. Matsubara et al have used this bone marrow implantation (BMI) technique in humans with peripheral arterial disease and have had some success in reducing ischemic symptoms4 However, as yet there have not been any reports on the relationship between the number of implanted bone marrow cells and the effects of BMI. Since mononuclear cells and CD34-positive cells affect the number of EPC, which play a major role in revascularization, it is likely that there is a direct relationship between the number of mononuclear cells or CD34-positive cells and the clinical efficacy of BMI.

In the present study, we have assessed the degree of CD34-positivity in the implanted bone marrow mononuclear cells, and have correlated the total number of mononuclear cells and CD34-positive cells with the clinical efficacy of BMI.

Methods

Patients  The entry criteria for patients to be enrolled in the present study were that they had symptoms of chronic limb ischemia, including severe intermittent claudication, rest pain or non-healing ischemic ulcers, but were not considered to be suitable candidates for non-surgical or surgical revascularization. Patients with poorly controlled diabetes mellitus (hemoglobinA1c>6.5% and proliferative retinopathy) or with evidence of a malignant disorder during the

previous 5 years were excluded. We obtained written informed consent from all patients. Prior to the commencement of the present study, the protocol had been approved by the ethics committees of all the participating universities.

**Procedures**

The primary focus of the clinical trial was the safety and efficacy of the treatment, as defined by an improvement in ankle-brachial pressure index (ABI), transcutaneous oxygen pressure (TcO2), and symptoms such as relief of rest pain, pain-free walking, and skin ulceration. Under general anesthesia, between 500 and 1,000 ml of bone marrow was collected from each patient. The mononuclear cells were separated to about 50 ml. The cells were implanted into the ischemic leg by means of an intramuscular injection using an Oxymonitor (PO-850, Sumitomo-Hightechs, Tokyo, Japan) (normal value >60 mmHg). The TcO2 was measured in a supine position using an Oxymonitor (PO-850, Sumitomo-Hightechs, Tokyo, Japan) (normal value >60 mmHg). The ABI and TcO2 were defined as the change in ABI or TcO2 between the pre-treatment measurement and that obtained 4 weeks after treatment. Digital subtraction angiography was also performed 1 week before and 4 weeks after treatment. Throughout the present study, the amount and injection velocity of the contrast medium and the position of the catheter tip, were strictly controlled. The degree of collateral vessel formation was assessed by 2 radiologists and a vascular surgeon, who were not otherwise involved in the study and who were not able to access other information about study participants.

**Statistical Analysis**

Changes in the variables measured were analyzed using a paired t-test, and the degree of correlation was assessed using Pearson’s correlation coefficient and Fisher’s Z-transformation test. Results were expressed as the mean ± SD, and were considered to be statistically significant when the value of p was less than 0.05.

**Results**

The profiles of the 8 patients treated with BMI and the clinical effects are shown in Tables 1 and 2, respectively. The mean numbers of implanted mononuclear cells and CD34-positive cells were 6.04±1.58×10^6/kg and 1.04±0.60×10^6/kg, respectively. An improvement in symptoms, such as relief of rest pain or healing of ulceration, was observed in all the patients. Digital subtraction angiographies showed an increase of small blood vessels in 6 of the

8 patients (Fig 1). Four weeks after treatment, the mean ABI increased from 0.54±0.47 to 0.61±0.50 (p<0.05, Fig 2). The TcO2 also increased from 28.4±15.4 mmHg to 37.1±24.4 mmHg at 2 weeks after treatment (p<0.05), and a further increase to 31.9±17.3 mmHg was found at 4 weeks (p<0.05, Fig 3). As shown in Fig 4 (ΔABI) and Fig 5 (ΔTcO2), there was a significant correlation between the number of CD34-positive cells and ΔABI (p<0.05).

**Discussion**

Initially, gene and cell therapy were novel therapeutic options, but these have now become reality. When this type of therapy is used for peripheral arterial disease, Isner has described it as “therapeutic angiogenesis.” Gene therapy using vascular endothelial growth factor (VEGF) has been assessed in a small open-label phase I study and was initially found to be successful. However, a subsequent randomized placebo-controlled trial was unable to confirm the effectiveness of VEGF therapy. The regeneration of blood vessels may be influenced by a number of factors and involve several steps. It is therefore likely that it is not a single factor, but a combination of individual growth factors and cytokines that are required for the coordinated growth of new vessels. For example, angiopoietin 1 (Ang-1) and angiopoietin 2 (Ang-2) have an integrated role in angiogenesis, with the sprouting and elongation of the endothelium being dependent on a higher concentration of Ang-2 compared with Ang-1. A subsequent switch in this balance, with an increase in Ang-1 compared to Ang-2, promotes the alignment of the new endothelium alongside the mural cells during maturation. However, the development of cell therapy may be able to supersede the complex strategy that is required in combination gene therapy. In BMI, supplied cells include not only stem cells and precursor cells as a source of regenerating tissue, but also accessory cells that support angiogenesis and vasculogenesis by producing several growth factors and cytokines in situ. The CD34-negative cells and non-EPC that are included in the bone marrow aspirate, and are subsequently implanted, produce several angiogenic factors such as VEGF, basic fibroblast growth factor, and Ang-1. In vitro, vasculogenesis from purified CD34-positive cells was supported and augmented by the addition and co-culture of the cells with...
a CD34-negative bone marrow fraction. On the basis of this finding, it is likely that the intercellular communication between EPCs and accessory cells is important in the process through which EPC differentiate and develop into physiological vascularization. Hence, BMI cell therapy is considered to be an in vivo therapy with EPC-implantation in combination with cytokine administration.

In recent reports from a number of institutions, a variety of different approaches have been suggested for the use of stem cell implantation in the treatment of peripheral ischemic disease. These approaches have included the implantation of bone-marrow-derived mononuclear cells (BM-MNC), CD34-positive cells purified from bone marrow cells, peripheral blood mononuclear cells (PB-MNC), and CD34-positive cells from blood. The effect of PB-MNCs is controversial. Matsubara et al have shown that implantation of PB-MNCs is less effective, presumably due to the low frequency of CD34-positive cells in peripheral blood, where the prevalence is approximately 500-fold lower than BM-MNC. In contrast, the angiogenic effect of PB-MNC implantation was more than a half (72%) of the effect of BM-MNC in an in vivo animal model, despite the conclusion difference in the CD34-positive rate (CD34-positive cells in BM-MNC and PB-MNC are 2.4% and 0.02%, respectively). Hence, when BM-MNC and BM-MNC are compared, a CD34-positive rate is not crucial and the angiogenic effect of BMI may arise due to angiogenic cytokine-production in accessory cells in BM-MNC rather than implanted CD34-positive cells. It is also noted that endothelial cells develop from bone marrow mononuclear cells through “trans-differentiation” more efficiently than from CD34-positive cells through maturation. In the present study, we have shown that the number of implanted CD34-positive cells, but not the total MNC, is one of the principal factors that influence the efficacy of BMI. The CD34-positive rate in bone marrow aspirate is 1.5 to 2.5% of total nucleated cells and 2 to 3% of MNC, while that in implanted BM-MNC was 0.4 to 2.4% (Table 2). Bone marrow cells are generally diluted by peripheral blood cells in the bone marrow collection procedure; hence the CD34-positive rate is also an indicator of bone marrow purity in implanted cells. Therefore, implanted cytokine-producing accessory cells also correlate with total implanted CD34-positive cells. Bone marrow consists of hematopoietic cells, stem cells, progenitor cells, and accessory cells producing angiogenic cytokines, so that angiogenic therapy using BM-MNC was superior to that using PB-MNC in animal models. Also the implanted CD34-positive cell number is an indicator of EPC as well as cytokine-producing accessory cells.

Conclusions

In summary, BMI was performed in 8 patients with arteriosclerosis obliterans. There was an improvement in symptoms, including ABI and TcO2 in all these patients. There was a significant correlation between the number of implanted CD34-positive cells and the efficacy of BMI.
