Surgical Treatment for Primary Cardiac Leiomyosarcoma Causing Right Ventricular Outflow Obstruction

Kazunori Ishikawa, MD*; Shuichiro Takanashi, MD; Wahei Mihara, MD; Toshihiro Fukui, MD; Yasuyuki Hosoda, MD

A 55-year-old man was admitted to another hospital because of dry cough and dyspnea that rapidly worsened before admission. Chest computed tomography revealed a low-density mass that nearly obstructed the main pulmonary arterial trunk. Pulmonary thromboembolism was suspected and treated with catheter-directed thrombolysis therapy. Despite optimal thrombolysis and anticoagulant therapy, his symptoms persisted. He was referred for further examination and possible surgery for presumed pulmonary thromboembolism. The mass appeared more likely to be a tumor than a thrombus on careful analysis of the magnetic resonance imaging. At surgery, the anterior wall of the main pulmonary arterial trunk, the pulmonary valve, annulus, and the right ventricular outflow tract were all invaded by what was found to be a tumor and were resected under conventional cardiopulmonary bypass. The resected area was reconstructed with a 25-mm-diameter bioprosthetic valve and Xenomedica patch. Final pathological diagnosis was primary cardiac leiomyosarcoma involving the pulmonary valve. Postoperative course was uneventful, and he was discharged 11 days after surgery without adjuvant therapy because he refused it. Ten months later, the patient was well, but a chest X-ray revealed some coin lesions in the bilateral lung fields that were thought to be metastatic tumor. (Circ J 2005; 69: 121–123)

Key Words: Adjuvant therapy; Primary cardiac leiomyosarcoma; Thromboembolism

Primary cardiac leiomyosarcoma is extremely rare, constituting less than 0.25% of all cardiac tumors, but it has a lethal prognosis even if surgical resection, with or without adjuvant therapy, is performed. Only a few cases of surgical resection of cardiac leiomyosarcoma have been reported. We present a case of surgical resection of a primary cardiac leiomyosarcoma involving the pulmonary valve, which was reconstructed with a bioprosthetic valve and Xenomedica patch.

Case Report

A 55-year-old man was admitted to another hospital because of dry cough and exertional breathlessness that had rapidly worsened over the previous 1–2 weeks. He had no remarkable medical history. A computed tomographic (CT) examination of the chest revealed a filling defect that almost completely obstructed the main pulmonary arterial trunk.

A diagnosis of pulmonary thromboembolism was assumed, and the patient was treated with catheter-directed thrombolysis therapy over 3 days. However, his dyspnea and shortness of breath worsened despite an optimal regimen of thrombolytic and anticoagulation therapy. The patient was referred to us for further evaluation and possible surgical management of the presumed pulmonary thromboembolism.

Upon admission, laboratory results showed elevated lactate dehydrogenase (785 U/L) and liver enzymes (AST 49 U/L, ALT 95 U/L). Chest X-ray showed mild cardiomegaly with a cardiothoracic ratio of 52%. The patient underwent magnetic resonance imaging (MRI) of the chest, which revealed a solid mass at the pulmonary valve, measuring approximately 50×40×30 mm with low signal intensity on T1-weighted image and increased signal intensity on T2-weighted image, that appeared to be invading the main pulmonary arterial trunk (Fig 1a,b). There was no evidence of distal thromboembolism in either of the pulmonary arteries. Because the mass appeared to be a tumor rather than a thrombus, the possibility of malignancy was raised. Transthoracic echocardiography disclosed a large mass involving the pulmonary valve and extending to the main pulmonary arterial trunk, enlargement of the right ventricle (end-diastolic diameter, 52 mm), and displacement of the ventricular septum toward the left ventricle. The mass almost completely obstructed the main pulmonary arterial trunk (Fig 1c), and right ventricular failure was suspected. The patient was scheduled to undergo surgery for tumor extirpation and histological evaluation of the mass.

At surgery, a hard mass was palpated in the slightly dilated main pulmonary arterial trunk. Conventional cardiopulmonary bypass was established with ascending aortic perfusion and bicaval drainage through a median sternotomy. After the heart was arrested, the main pulmonary arterial trunk was incised longitudinally from just above the pulmonary valve to the bifurcation, whereupon a whitish tumor originating from the pulmonary valve was found to have almost completely blocked the lumen of the main pulmonary arterial trunk and invaded its anterior wall. We also opened the right pulmonary artery longitudinally behind the ascending aorta and recognized scattered tumor on the posterior wall of the right main pulmonary artery that extended far distally, at least to the hilum, such that radical resection appeared impossible. The mass was resected as completely as possible, together with the anterior wall of
the main pulmonary arterial trunk, the pulmonary valve, annulus, and right ventricular outflow tract (Fig 2a,b). The resected area was reconstructed with a 25-mm diameter bioprosthetic valve (Carpentier-Edwards PERIMOUNT bioprosthesis, Edwards-Lifesciences, Irvine, CA, USA) and Xenomedica patch (Baxter Healthcare Corp, Horw, Switzerland). After the procedure was completed, the patient was easily weaned from bypass.

Histopathological examination revealed spindle-type cells with a high rate of mitosis, indicating malignancy.
Primary cardiac leiomyosarcoma is rare; approximately 25% are malignant and almost all of them are sarcoma.1 There are many types of sarcomas, including rhabdomyosarcoma, osteosarcoma, fibrosarcoma, angiosarcoma, liposarcoma, and leiomyosarcoma, but primary leiomyosarcoma of the heart is the rarest among them, constituting less than 0.25% of all cardiac tumors.2 In the literature only 54 cases have been reported since 1966.3

Diagnosis of primary cardiac leiomyosarcoma originating from the right ventricular outflow tract is very difficult because the clinical symptoms are usually similar to those of pulmonary thromboembolism, which makes not only early diagnosis difficult but also leads to misdiagnosis.4 Unfortunately, clinical presentation varies, from dyspnea on effort with or without, dry cough to chest pain and hemoptysis, which occur mostly only in the advanced stage of the disease.5 Most previous cases have been diagnosed post mortem, but recent advances in diagnostic techniques such as echocardiography, CT, and MRI have made it possible to diagnose it in living patients. Several reports suggest that CT and MRI may be the most useful modalities for differentiation between tumor and thrombotic material.6 Therefore, the mass appeared to be a tumor rather than a thrombus and most likely malignant. In particular, heterogenous enhancement on MRI after application of gadolinium-diethylene-triamine-pentaacetic acid is characteristic of a vascularized tumor. The usefulness of biopsy via cardiac catheterization to make an accurate preoperative diagnosis has also been reported in the literature.8 In the present case, a solid mass was presented with low signal intensity on T1-weighted image and increased signal intensity on T2-weighted image by MRI and there was no evidence of distal thromboembolism in either of the pulmonary arteries on CT or MRI examination.

The mean survival time of patients with leiomyosarcoma of the heart is 6 months after diagnosis9,10 and quality of life is poor because of progressive right heart dysfunction.10,11 Because it originates from the heart itself, the tumor is not easy to resect completely. Despite apparently complete surgical excision, most patients die within the first year after diagnosis because of local tumor relapse or metastatic disease.11,12 The aims of the surgical procedure are to relieve symptoms and to offer adequate palliation. In the present patient, because of the extensive distribution of the tumor in the posterior wall of the right main pulmonary artery, radical tumor resection was not possible. Extended resection followed by reconstruction with the bioprosthetic valve and Xenomedica patch was performed with the hope of relief of his symptoms.

The fact that some patients have survived more than 2 years after surgery with adjuvant therapy8,11,13 suggests that the combination of adjuvant therapy and excision of the tumor is somewhat effective, but the actual effectiveness and indications for such therapy are currently not clearly established because of the rarity of experience with leiomyosarcoma.

### Conclusion

We report a surgical case of primary cardiac leiomyosarcoma involving the pulmonary valve. Ten months after resection of the tumor, the patient was well with almost no limitations in his daily life. There was no evidence of recurrence of the tumor on his heart itself, but a chest X-ray revealed some coin lesions in the bilateral lung fields that we presume to be metastatic tumor. Further careful follow-up of this patient is necessary.
