Cutoff and Target Values for Intra-Abdominal Fat Area for Prevention of Metabolic Disorders in Pre- and Post-Menopausal Obese Women Before and After Weight Reduction

Ryosuke Shigematsu, PhD; Tomohiro Okura, PhD*; Syuzo Kumagai, PhD**; Yuko Kai, PhD***,‡‡; Teruo Hiyama, MD†; Haruka Sasaki, MD††; Hitoshi Amagai, MSc‡; Kiyoji Tanaka, PhD*,*

Background  The Japan Society for the Study of Obesity originally proposed a cutoff value of >100 cm² for the intra-abdominal fat area (IFA) as a definition for “visceral fat obesity” in Japanese adults. There are no studies on the cutoff or target values after weight reduction in pre- and post-menopausal women.

Methods and Results  In the present study 149 pre-menopausal obese women (PreM, 43.3 years, 27.3 kg/m²) and 58 post-menopausal women (PostM, 53.9 years, 27.7 kg/m²) participated in a 14-week weight reduction program. The IFA was measured by computed tomography. The program induced significant reductions in body weight (8.6 kg in PreM and 7.8 kg in PostM). The IFA decreased significantly from 80.4±41.3 to 50.7±23.8 (PreM) and from 115.4±38.0 to 75.7±30.5 (PostM).

Conclusions  The receiver-operating characteristic curve analyses revealed that the appropriate cutoff values were 80 cm² (PreM) and 110 cm² (PostM) before the program, and after the program the appropriate target values were determined as 60 and 70 cm², respectively.  

Key Words: Diet; Exercise; Fat body; Menopause; Metabolic syndrome

There are several studies of the effects of menopause on the relationship of IF with metabolic diseases. Excess IF deposition is more prevalent in post-menopausal women than in pre-menopausal women although it occurs more frequently in males of all ages. Hunter et al6 and Gower et al showed that the IFA and the risk of coronary heart disease (CHD) were positively correlated and that each average in post-menopausal women was higher than that in pre-menopausal women. The results of the study by Rebuffe-Scrive et al suggest that one of the reasons for this phenomenon is the more pronounced activation of lipoprotein lipase in the omental adipose tissue of post-menopausal women than in that of pre-menopausal women. The cutoff value for the IFA derived by JASSO1 was defined using a combination of pre- and post-menopausal women; the standards were, therefore, not established while considering the presence of menopause.

Based on these results, the current study assesses JASSO’s visceral fat obesity IFA cutoff value of 100 cm² in pre- and post-menopausal women and also assesses the IFA target value after a weight reduction program. We tested 2 related hypotheses: (1) the cutoff value would be valid when applied to a group consisting of only pre- or post-menopausal women and (2) it would remain valid in each group after reducing the IFA.

Methods

Participants  Advertisements were placed in local newspapers and on bulletin boards in Toride City in Ibaraki Prefecture and Abiko City in Chiba Prefecture in Japan to locate potential participants.
participants with a desire to lose weight. Those who responded to the advertisements were interviewed by telephone. The participants supplied information on demographics, menstrual status, and medical history. They were excluded from the study if their weight had been unstable for the past 6 months, if they had attended any weight reduction programs in the past year, or if they were breast feeding or pregnant. A study physician confirmed if participants were possibly pregnant. After applying the exclusion criteria to potential participants, the selected participants (n=220) received the details of the study’s purpose and protocol. Oral informed consent, following the Helsinki Declaration principles and approved by the Higashi Toride Hospital Review Board, was obtained from each person. We defined “menopause” as the status of no menses for 1 year prior to the study. “Pre-menopause” was used define individuals who were not experiencing menopause. Therefore, the pre-menopausal group consisted of women who declared having menses in the year prior to the study (PreM). The post-menopausal group included those women who had not had menses for more than 1 year prior to the beginning of the study (PostM).

IFA
We measured the IFA and subcutaneous fat area (SFA) at the level of the umbilicus using cross-sectional CT (SCT-6800TX; Shimadzu, Japan). Scans were performed with the participants in the supine position. Details of the scanning have been reported by Tokunaga et al.10 and Yoshizumi et al.10 Measurements taken before and after the program were conducted at the same time of day by the same technician to minimize technical error. The IFA and SFA were calculated using a computer-software program (FatScan; N2system, Japan).10 The intra-class correlation for repeated IFA determinations in the laboratory (Institute of Health and Sport Sciences, University of Tsukuba) is 0.99 (n=30).

Obesity-Related Metabolic Disorders
The obesity-related metabolic disorders were defined as follows: accumulation of IF (waist circumference ≥90 cm in female) plus 2 or more co-morbidities consisting of (i) triacylglycerol (TG) ≥150 mg/dl and/or high-density lipoprotein cholesterol (HDLC) <40 mg/dl, (ii) systolic blood pressure (SBP) ≥130 mmHg or diastolic blood pressure (DBP) ≥85 mmHg, or (iii) fasting plasma glucose ≥110 mg/dl.12 These biochemical assays were performed on approximately 10 ml of blood drawn from each participant after an overnight fast. The blood assays were analyzed by the electrochemical enzymatic method using a lactate analyzer (model 23L, YSI Inc, OH, USA). For establishing LT, the log (oxygen uptake)–log (lactate) transformation method was used.16 Exercise was consistently performed for 45 min throughout the 14 weeks, but the intensity was progressively increased. In the first 2 weeks, the bench-stepping instructor targeted the intensity as described. After the 3rd week, the instructor progressively increased the intensity by increasing the cadence of the step and adding more dynamic movements. Ratings of the perceived exertion (RPE)17 by all participants were also monitored during the bench stepping. Based on their RPE, the instructor moderated the intensity as “somewhat hard” to “hard,” which corresponded to LT or a little above LT.18

Statistical Analysis
Differences in variables between the beginning and end of the program were tested in each group by using Student’s paired t-tests. Data were analyzed with the SPSS 11.01J statistical software package (SPSS, Chicago, IL, USA), and P-values less than 0.05 were considered statistically significant.

Weight Reduction Program
A 14-week weight reduction program was monitored by

a physician, dietician, exercise instructors, and graduate school students majoring in exercise intervention. After the baseline assessment, participants received instruction on the diet program, which comprised weekly 90-min diet consultations, at which a diet-recording notebook and several handouts were given to participants to help them adhere to the principles of the daily diet. They were asked to take a well-balanced supplemental food product (MicroDiet; Sunny Health Co, Ltd, Japan) daily as 1 of their meals, preferably as lunch or dinner. The MicroDiet, which includes various amino acids, vitamins, and minerals, was developed for very low-energy diets. To prevent boredom, the MicroDiet was served in 7 flavors: coffee, milk tea, cocoa, yogurt, banana, strawberry, and apple. Participants received packages consisting of 7 meals (each flavor) once a week. The nutritional values for each flavor were slightly different (ie, there was a range for protein (20.6–21.5 g), carbohydrate (15.0–18.1 g), fat (1.6–3.0 g), and energy (169–173 kcal) for each meal). The diet records were obtained from 86 participants (60 in the PreM group, 26 in the PostM group), who were randomly selected. One week before the study, the participants were asked to record everything they had eaten for the 3 days prior to the study. Furthermore, they were asked to record their diets for 3 days during week 7, the midpoint of the intervention.

The exercise program included 3 weekly 45-min sessions. During the first and second weeks of the 14-week program, exercise sessions consisted mainly of walking and stretching, with the gradual addition of a bench-stepping exercise as the main element. Thereafter, the exercise session consisted of a 10-min warm-up, 25-min bench stepping, and a 10-min cool-down. The bench stepping targeted an exercise intensity in which the participant’s heart rate reached a level 10–15% higher than the level corresponding to her lactate threshold (LT). The LT was defined as the point at which blood lactate concentration maintained a non-linear increase above the level at rest. To determine LT, a series of venous blood samples (1 ml each) was drawn from the antecubital vein every minute during a maximal cycling exercise test, which was done with an accompanying electrocardiogram as a baseline assessment. All blood samples were analyzed by the electrochemical enzymatic method using a lactate analyzer (model 23L, YSI Inc, OH, USA). For establishing LT, the log (oxygen uptake)–log (lactate) transformation method was used.16

Exercise was consistently performed for 45 min throughout the 14 weeks, but the intensity was progressively increased. In the first 2 weeks, the bench-stepping instructor targeted the intensity as described. After the 3rd week, the instructor progressively increased the intensity by increasing the cadence of the step and adding more dynamic movements. Ratings of the perceived exertion (RPE) by all participants were also monitored during the bench stepping. Based on their RPE, the instructor moderated the intensity as “somewhat hard” to “hard,” which corresponded to LT or a little above LT.

Statistical Analysis
Differences in variables between the beginning and end of the program were tested in each group by using Student’s paired t-tests. Data were analyzed with the SPSS 11.01J statistical software package (SPSS, Chicago, IL, USA), and P-values less than 0.05 were considered statistically significant.

To assess the cutoff value (before weight reduction) and
the target value (after weight reduction) for IFA, receiver-operating characteristic (ROC) curve analysis was applied to the data derived from the IFA and the number of metabolic disorders. By provisionally varying the cutoff/target values of IFA, we calculated the sensitivities and specificities for each value. Sensitivity was defined as the proportion of participants having no disorders who had an IFA equal to or greater than the provisional value to all participants having a given disorder. Specificity was defined as the proportion of participants having no disorders who also had an IFA that fell below the provisional value to all participants having a given disorder. Consequently, 207 women completed the study (Table 1), and attendance averaged 92% (range 83–100%).

The sensitivities and specificities were calculated for every 10 cm² of IFA from 30 to 140 cm². After weight reduction, the sensitivity of IFA was averaged 92% (range 83–100%). Of the 220 women originally enrolled in this study, 13 dropped out because they moved out of the area, needed to care for a family member, or felt fatigued. Consequently, 207 women completed the study (Table 1), and attendance averaged 92% (range 83–100%).

Results

Of the 220 women originally enrolled in this study, 13 dropped out because they moved out of the area, needed to care for a family member, or felt fatigued. Consequently, 207 women completed the study (Table 1), and attendance averaged 92% (range 83–100%).

There were significant decreases in the anthropometric variables, IFA, SFA, metabolic variables, and blood pressures in each group (Table 2). Total body composition analysis revealed that the reduction in body weight was mostly from loss of body fat. The reduction in fat-free mass
The daily average energy intake in the PreM group was 2,100±354 kcal at 1 week before the study and it decreased significantly to 1,870±394 kcal to 1,029±152 kcal. The PostM group significantly reduced their energy intake from 1,870±394 kcal to 1,029±152 kcal. The daily protein intake in the PreM group was 78.1±15.1 g, and it decreased significantly to 70.3±14.2 g. In the PostM group, it decreased significantly from 66.3±14.9 to 53.1±9.9 g in the PreM group and from 56.6±20.4 g to 27.4±6.2 g in the PostM group. The daily carbohydrate intake also decreased significantly from 66.3±14.9 g to 33.1±9.9 g in the PreM group and from 56.6±20.4 g to 27.4±6.2 g in the PostM group. The daily carbohydrate intake also decreased significantly from 285.5±61.2 g to 147.5±31.3 g in the PreM group and from 272.3±94.1 g to 136.1±23.8 g in the PostM group.

The percentage of participants that exceeded each criterion of the metabolic disorders is shown in Table 3. More than 50% of the participants had a high abdominal circumference before the program (PreM, 75%; PostM, 86%). The most frequent disorder in both groups was hypertension, with hyper-SBP (PreM, 50%; PostM, 67%) and hyper DBP (PreM, 35%; PostM, 48%). After the program, the percentages of all disorders, except for hypo-HDLC in the PreM group, decreased. The characteristics of the 12 provisional cutoff/target values for IFA from 30 cm² to 140 cm² are presented in Table 4. Sensitivities before the program ranged from 0.16 to 0.96 in the PreM group and from 0.29 to 1.00 in the PostM group. Specificities ranged from 0.04 to 0.97 for the PreM group and from 0.07 to 0.99 for the PostM group. The products obtained by multiplying the sensitivity by the specificity at each provisional value ranged from 0.04 to 0.97 in the PreM group and from 0.07 to 1.00 in the PostM group. The largest products of sensitivity and specificity were found at 80 cm² (0.47) for the PreM group and 110 cm² (0.52) for the PostM group. Therefore, the cutoff values with the best equilibrium between sensitivity and specificity approached 80 cm² in the PreM group and 110 cm² in the PostM group before weight reduction. Using the same method of analysis, the most valid target values after the weight reduction program were determined to be 60 cm² for the PreM group and 70 cm² for the PostM group.
There seem to be other factors in addition to estrogen affecting the risk of metabolic disease; for example, aging, which correlates to an increase in IFA.2,6,23 and adiponectin24 may be a factor.

In previous studies, a cross-sectional design was used to determine an IFA cutoff value,19,20 but because it is also important to determine a target IFA value for reducing the risk of metabolic disease, an intervention design was used in the current study. The IFA relates to the risk of obesity-related metabolic disorders; therefore, we assumed that the target values after weight reduction would remain the same as before the program, but they were lower. Although the reasons for this are unclear, we speculate that once a person is suffering from a metabolic disorder, a significant reduction in IFA may not be enough in itself to ameliorate the situation.

**Study Limitations**

The reasons for the relatively low sensitivities and specificities derived from IFA and metabolic disorders are unclear. Some unmeasured factors, such as diet and the genetic effect of metabolic disorders, may play a part. Furthermore, homeostasis was not maintained during and just after the weight loss. Another limitation is that the number of participants was small and that the mean body mass index or IFA was not very high, although most participants were obese. Future studies should include a larger number of extremely obese participants to verify the target values for risk of IFA after weight reduction. A significant decrease in HDLC in the PreM group was found after weight reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet. Hagan et al.25 reported that HDLC decreased as middle-aged reduction, which may have been caused by the diet.

In conclusion, this study presents the cutoff values for IFA in both pre- and post-menopausal obese women, as useful for the diagnosis of obesity-related metabolic disorders. Before weight reduction, the cutoff values with the best equilibrium were 80 cm² for pre-menopausal women and 110 cm² for post-menopausal women. After weight reduction, the target values shifted to 60 cm² and 70 cm², respectively. Using these values, persons diagnosed with visceral fat obesity can clearly see the benefits of engaging in a diet and exercise program. Furthermore, awareness of a target value makes adherence to the program more likely.
