Long-Term Prognosis of Dilated Cardiomyopathy Revisited
— An Improvement in Survival Over the Past 20 Years —

Yoshihisa Matsumura, MD; Jun Takata, MD; Hiroaki Kitakada, MD; Toru Kubo, MD; Yuichi Baba, MD; Eri Hoshikawa, MD; Tomoyuki Hamada, MD; Makoto Okawa, MD; Nobuhiko Hitomi, MD; Kyoko Sato, MD; Naohito Yamasaki, MD; Toshikazu Yabe, MD; Takashi Furuno, MD; Masanori Nishinaga, MD; Yoshinori Doi, MD

Background  Because of their favorable prognostic effects, angiotensin converting enzyme inhibitors (ACEI), angiotensin II receptor blockers (ARB) and β blockers have become background therapy in dilated cardiomyopathy (DCM). However, there are few reports concerning the long-term prognosis of Japanese patients with DCM in relation to these treatments.

Methods and Results  One hundred and fifty patients with DCM were divided into 2 groups: group A (n=46) (diagnosis: 1982–1989) and group B (n=104) (diagnosis: 1990–2002). During follow-up period of 6.9±4.8 years, 62 patients died and 1 patient had a heart transplant. The survival rate at 5 and 10 years was 60.9% and 34.8%, respectively, in group A patients, and 80.9% and 65.3%, respectively, in group B patients (p=0.0079). In group A patients, ACEI/ARB or β blockers were less frequently used (p<0.0001), whereas antiarrhythmics (class Ia or Ib) were more often used (p<0.0001). The patients treated with ACEI/ARB and β blockers showed a better survival rate than those without (p<0.0001). The patients with antiarrhythmics showed a worse survival rate than those without (p<0.0001).

Conclusion  The prognosis of Japanese patients with DCM has significantly improved over the past 20 years. This improvement may be explained partly through the increased use of ACEI/ARB and β blockers and a declining use of antiarrhythmics. (Circ J 2006; 70: 376–383)

Key Words: Dilated cardiomyopathy; Prognosis

I diopathic dilated cardiomyopathy had a poor prognosis in the past.1–5 Many randomized clinical trials performed in the United States of America and Europe have shown the beneficial effects of angiotensin converting enzyme inhibitors (ACEI)6–9, angiotensin II receptor blockers (ARB)10–13 and β blockers on the survival of the patients with congestive heart failure.14–19 In contrast, only 2 small randomized studies of ARB (candesartan)20 and β blocker (carvedilol) have been performed in Japan to date in patients with congestive heart failure.21 There are no randomized studies of ACEI.

Although there are few reports concerning the long-term prognosis of Japanese patients with dilated cardiomyopathy (DCM) after ACEI, ARB and β blockers became major components of background therapy in the management of all stages of patients with DCM, the beneficial effects of ACEI/ARB and β blockers on the prognosis of Japanese patients with DCM have not clearly been shown in these studies.22–28 Some studies even failed to reveal favorable effects of ACEI or β blockers on the survival of Japanese patients with DCM.23,27,28 It also remains uncertain whether antiarrhythmics or spironolactone have significant effects on the prognosis of Japanese patients with DCM.23

though previous studies in Western countries have shown an adverse effect of antiarrhythmics30–34 and a favorable effect of spironolactone on the prognosis.35

Thus, little information exists concerning changes in the prognosis of Japanese patients with DCM, to whom the recent trend in the survival should be informed, in relation to treatment.

The purpose of the present study was to analyze the changes in the long-term prognosis in Japanese patients with DCM over the past 20 years and to identify the factors that might have influenced survival.

Methods

Study Patients  We studied 150 patients (115 men and 35 women, aged 20–83 (mean=59±11) years) with idiopathic DCM who were referred to our hospital between 1982 and 2002. Ninety patients were in the New York Heart Association functional class I or II, and 60 patients were in class III or IV. A careful history was taken from all the patients, and they were given a physical examination, blood test, chest X ray, standard echocardiography, exercise stress test and cardiac catheterization, including coronary angiography and biplane left ventriculography. The diagnostic criteria were: (1) a dilated left ventricle (end-diastolic dimension (LVDD) >55 mm) with fractional shortening (LVFS) <25%; and (2) exclusion of patients with acute myocarditis, specific heart muscle disease, general systemic disease, significant coronary artery stenosis (defined as diameter narrowing of >50% in any of the major coronary arteries or their
branches), valvular disease, sensitivity/toxic reactions and a history of excessive alcohol intake. Coronary angiography was performed in 138 patients; none had significant coronary artery stenosis. Exercise electrocardiography and/or thallium-201 myocardial scintigraphy were negative for the remaining 12 patients who also showed no clinical or electrocardiographic (at rest) evidence of coronary artery disease. Atrial fibrillation was found in 35 patients.

Standard background therapy before 1990 consisted of diuretic agents, digoxin and some vasodilators. After 1990, there have been an increase in the use of ACEI and β-blockers, and a decrease in the use of antiarrhythmics (class Ia and Ib) at our hospital. Therefore, we divided the patients into 2 groups according to their date of initial diagnosis: group A: 46 patients diagnosed between January 1982 and December 1989; group B: 104 patients diagnosed between January 1990 and December 2002.

Follow-up

End points for follow-up were death or heart transplantation. For the purpose of analysis, patients who died of cardiac causes (sudden death and heart failure death) or had a heart transplant were regarded as one group. The follow-up data were obtained by regular visits at our hospital, interviews with referring physicians and/or chart reviews, and by telephone contact with the patients or their relatives. The study closed on 31 August 2004.

Statistical Analysis

The results were expressed as mean±SD. A chi-square test was used to compare categorical variables. Group data were compared using the unpaired Student’s t-test. Survival estimates were obtained using the Kaplan–Meier method. The severity of left ventricular (LV) systolic dysfunction, determined by echocardiogram, was used to stratify the survival curves of the patients in groups A and B. The patients in each group were divided into 2 strata—those with LVFS >15% and those with LVFS ≤15%—as the mean value of LVFS was 15% in all the patients.

The multivariate Cox proportional hazards model was used to analyze the relationship between survival and prognostic indices. A p value <0.05 was considered statistically significant.

Results

Baseline Characteristics

The baseline clinical characteristics of the patients in groups A and B are shown in Table 1. There were no differences in clinical findings except medical treatment. In the group A, ACEI/ARB or β-blockers were less frequently
used than in group B (p<0.0001), whereas antiarrhythmics (class Ia or Ib) were more often used (p<0.0001). Also, in group A, spironolactone were more often used than in group B (p<0.0001). ACEI were administered in 100 patients, and ARB administered in 9 patients. Enalapril (2.5–10 (mean 5.3±1.7) mg daily) and captopril (25–37.5 (mean 31.0±8.4) mg daily) were the most frequently used ACEI (74%). Losartan (25–50 (mean 30.0±11.1) mg daily) was the most frequently used ARB (56%). Beta blockers were administered in 55 patients: carvedilol (2.5–20 (mean 9.5±4.9) mg daily) in 30 patients and metoprolol (20–120 (mean 61.6±30.6) mg daily) in 25 patients.

The baseline echocardiographic and cardiac catheterization data of the patients in groups A and B are shown in Table 2. There were no differences in echocardiographic findings except LVDd and LV end-systolic dimension. There were no differences in hemodynamic findings except LV end-diastolic pressure (LVEDP).

Long-Term Prognosis (All-Cause Mortality and Cardiac Death)

During the follow-up period of 6.9±4.8 years, 62 patients died (40 cardiac, 12 non-cardiac and 10 unknown causes), 1 patient had a heart transplant and 87 patients survived (Fig 1). Of the 41 patients who died of cardiac cause or had a heart transplant, 27 were in the group A and 14 in the group B.

Kaplan–Meier analysis showed that survival curves for all-cause mortality and cardiac death were significantly worse in group A than in group B, respectively (Fig 2). The calculated survival rate for all-cause mortality at 5 and 10 years was 60.9% and 34.8%, respectively, in group A, and 80.9% and 65.3%, respectively, in group B (p=0.0079) (Table 3). The calculated survival rate for cardiac death at 5 and 10 years was 61.5% and 43.6%, respectively, in group A, and 88.2% and 81.0%, respectively, in group B (p=0.0002) (Table 3).

After stratification according to the severity of LV systolic dysfunction, the survival curves for cardiac death in the groups A and B were significantly different in 73 patients with LVFS >15%, though those for all-cause mortality were not (Fig 3). The survival curves for all-cause mortality and cardiac death in the groups A and B were also significantly different in 77 patients with LVFS ≤15% (Fig 4).

Cardiac Death and Medical Treatment

The incidence of cardiac death was significantly lower in patients treated with ACEI/ARB than in those without (p<
0.001) (Fig 5). It was also significantly lower in patients treated with β blockers than in those without (p=0.0019) (Fig 6).

The patients treated with ACEI/ARB and β blockers showed a better survival than those with ACEI/ARB only and those without (p<0.0001) (Fig 7).

The incidence of cardiac death was significantly higher in patients treated with antiarrhythmics than in those without (p<0.0001) (Fig 8). There was no significant difference in the incidence of cardiac death between patients with class
After stratification according to the severity of LV systolic dysfunction, this improvement in the survival was also more evident in patients with LVFS ≤15% (Fig. 4).

The survival curves for cardiac death in groups A and B were also significantly different in patients with LVFS >15%, though those for all-cause mortality were not (Fig. 3). This discrepancy may probably be associated with the fact that the patients more frequently died of non-cardiac and unknown causes in group B than in group A.

The survival rate at 5 years was 60.9% for all-cause mortality in group A (diagnosis: 1982–1989) (Table 3). This survival rate was similar to that in the previous reports. However, in group B (diagnosis: 1990–2002), the survival rate at 5 years was 80.9% for all-cause mortality. Also, the survival rate for cardiac death at 5 and 10 years was 61.5% and 43.6% in group A and 88.2% and 81.0% in the group B. These results suggest the long-term prognostic of Japanese patients with DCM has significantly improved over the past 20 years.

Factors Contributing to the Improvement in the Survival

The patients in group A had slightly larger LV sizes and higher LVEDP than those in group B, though other variables from echocardiography and cardiac catheterization were similar (Table 2). It is possible that the patients in group A had more advanced myocardial changes at diagnosis than those in group B. We also found an increase in the number of patients in group B compared to that in group A. Relatively earlier diagnosis might have been made in those in group B, though the age at diagnosis was similar between groups A and B.

ACEI and β blockers were less often used in group A than in group B, whereas antiarrhythmics were more often used in group A (Table 1). The patients treated with ACEI/ARB or β blockers showed a better survival than those without (Figs 5 and 6). Moreover, the patients treated both with ACEI/ARB and β blockers showed a better survival than those treated with ACEI/ARB only and those without (Fig 7). The patients treated with antiarrhythmics showed a worse survival than those without (Fig 8). These results indicate that an improvement in the long-term survival of patients with DCM can, at least in part, be explained by the advances in the pharmacologic treatment.

The Use of ACEI/ARB or β Blockers

ACEI/ARB Although ACEI and ARB have been believed to have favorable prognostic effects, the use of ACEI23,27,28 and ARB has not been shown to have favorable effects on the prognosis of Japanese patients with congestive heart failure.20 Azuma et al reported that the use of ACEI did not significantly affect long-term survival in patients with DCM.23 In the CHART study, the use of ACEI also did not improve the prognosis in Japanese patients with nonischemic cardiomyopathy.27,28 Despite these negative data in Japanese patients with DCM, the present study provided clear evidence that the use of ACEI/ARB had favorable effects on prognosis (Fig 5).

Beta Blockers There is little evidence that the use of β blockers has favorable effects on prognosis of Japanese patients with chronic heart failure. The MUCHA trial demonstrated that carvedilol therapy achieved improvement in the combined end point, which was all-cause mortality or cardiovascular hospitalization, in Japanese patients with chronic heart failure.21 However, it could not be fully determined whether carvedilol lowers the cardiac death in patients with DCM, since patients treated with carvedilol had a worse survival than those without during the early follow-up period (Fig 2).

In Japan, however, only 2 small randomized studies of ARB (candesartan)20 and β blocker (carvedilol) have been performed in patients with congestive heart failure.21 There are no randomized studies of the effects of using ACEI. Although previous studies in Japan have reported an improvement in the survival of patients with DCM, these studies included limitations such as a small number of patients, relatively short follow-up periods and end point of all-cause mortality (not cardiac death).22–28 Therefore, it is unresolved whether the long-term prognosis of Japanese patients with DCM has improved because of improved treatments.

In the present study, survival rates for all-cause mortality and cardiac death were significantly lower in group A than in group B, respectively (Fig. 2).

patients with chronic heart failure. Although the beneficial effects of β blockers on the prognosis of Japanese patients with DCM have been shown in the previous retrospective studies, the CHART study failed to reveal favorable effects from β blockers on prognosis of Japanese patients with nonischemic cardiomyopathy.

In the present study, β blockers had favorable effects on the prognosis of Japanese patients with DCM (Fig. 6). Moreover, the addition of β blockers was more beneficial to patients with DCM who had been treated with ACEI/ARB (Fig. 7). The Cox proportional hazard analysis also showed the disuse of ACEI/ARB and β blockers as the independent determinants of cardiac deaths (Table 4).

The Doses of ACEI/ARB or β Blockers

ACEI/ARB The targeting doses of ACEI or ARB are much higher in previous randomized clinical trials performed in the Unites States of America and Europe than those used in clinical practice in Japan. For example, in the CONSENSUS study, the target dose of ACEI (enalapril) was 40 mg daily. In the ELITE II trial, the dose of ACEI (captopril) was 150 mg daily, and that of ARB (losartan) was 50 mg daily.

It is still controversial whether low doses and high doses of ACEI have similar beneficial effects on prognosis in chronic heart failure. For example, Packer et al have reported that the use of high doses (32.5–35 mg daily) instead of low doses (2.5–5.0 mg daily) of ACEI (lisinopril) reduces the risk of major clinical events in patients with chronic heart failure. In contrast, in other studies, high doses (20 mg daily) of ACEI (enalapril) were not superior to low doses (5 mg daily) in the present study, the low dose of ACEI/ARB was effective in reducing the risk of cardiac death in Japanese patients with DCM (Fig. 5).

β Blockers The target doses of β blockers are also much higher in previous randomized clinical trials performed in the Unites States of America and Europe than those used for the treatment of congestive heart failure in Japan. In the MERIT-HF study, the target dose of metoprolol was 200 mg daily. In the US MOCHA trial, the target dose of carvedilol was 50 mg daily.

In Western countries, the recommended dose of carvedilol is 50 mg daily for maintenance treatment of congestive heart failure. In Japan, in the MUCHA trial, the low dose of carvedilol (5–20 mg daily) reduced the risk of all-cause mortality or cardiovascular hospitalization. The difference in the effective dose between patients in Japan and those in Western countries may depend on different drug absorption and metabolism, different β1 receptor sensitivity and different body size. The MUCHA trial suggested that the recommended dose of carvedilol for Japanese patients with congestive heart failure should range from 5 to 20 mg daily. In the present study, the low dose β blockers also achieved a marked reduction in the risk of cardiac death (Fig 6).

These results indicated that even the low dose regimens of ACEI/ARB or β blockers have favorable effects on prognosis of Japanese patients with DCM.

The Use of Antiarrhythmics

The studies performed in Western countries have shown adverse effects from antiarrhythmics (class I) on the survival of patients with congestive heart failure, probably because of negative inotropic effects and proarrhythmia. However, previous studies in Japan have not shown adverse effects of antiarrhythmics on the prognosis of patients with DCM. In the present study, the patients treated with antiarrhythmics (class Ia or Ib) showed a worse survival rate than those without (Fig 8). There was no significant difference in the incidence of cardiac death between patients treated with class Ia antiarrhythmics and those with Ib. There was no patient treated with amiodarone in this study.

The reasons for the use of antiarrhythmics were unclear because Holter electrocardiographic findings were not available for all the study patients. It may be possible that the presence of atrial and/or ventricular arrhythmias was associated with poor prognosis in patients with antiarrhythmics, though the incidence of atrial fibrillation at diagnosis was similar between the patients with antiarrhythmics and those without. Another possibility is the change of strategies for the use of arrhythmias.

Class Ia or Ib antiarrhythmics should be used with caution in the management of patients with DCM. Also, class Ic antiarrhythmics should not be used in patients with LV systolic dysfunction because of its negative inotropic effect and proarrhythmia. The Sicilian Gambit meetings suggested that the “upstream” approach to antiarrhythmic therapy should be considered first in patients with DCM who have arrhythmias. Environmental factors associated with arrhythmia, including pathogenic factors, hemodynamic load, myocardial perfusion and others, should be modified before the use of antiarrhythmics. The use of ACEI/ARB and β blockers is one of the “upstream” approaches to arrhythmias because of their effectiveness in preventing LV remodeling and improving LV systolic function. These changes of strategies for the arrhythmias might also be associated with the declined use of antiarrhythmics in the group B.

The Use of Spironolactone and Other Drugs

Spironolactone, digitalis and loop diuretics did not significantly affect long-term survival in this study, though a recent report has shown the favorable effect of spironolactone on the survival of patients with severe congestive heart failure. At first, the patients treated with spironolactone appeared to show a worse survival rate than those without in this study. However, spironolactone did not significantly affect long-term survival when the patients with antiarrhythmics were excluded from the analysis. The Cox proportional hazard analysis also did not show spironolactone as a significant determinant of cardiac death.

Predictors of Cardiac Death

The Cox proportional hazard analysis revealed that high LVEDP, the disuse of ACEI and β blockers, and the use of antiarrhythmics (class Ia or Ib) were the significant predictors of cardiac death (Table 4). These results suggest that the patients with high LVEDP, who probably have more advanced myocardial changes, show worse prognoses. The use of both ACEI and β blockers, and the disuse of antiarrhythmics (class Ia or Ib) could significantly improve the long-term survival of Japanese patients with DCM.

Clinical Implications

This awareness of the improvement in the survival rate of Japanese patients with DCM will help us provide up-to-date treatment information for the majority of patients with DCM. Both ACEI/ARB and β blockers should be strongly recommended as background therapy, whereas antiarrhyth-
mics (class Ia or Ib) should be used with caution in the management of patients with DCM.

**Limitations**

The present study was not prospective and randomized. The number of the subjects was small so some of the statistical analyses might have been affected. The improvement in the survival rate of the patients with DCM might be related to other factors such as earlier diagnosis, differences in the clinical characteristics of the patients at diagnosis and referral bias. There was an increase in the number of patients in group B. Relatively earlier diagnoses might have been made in those in group B, though the age at diagnosis was similar between groups A and B. The LVDD and LVDs were slightly larger, and LVEDP was also higher in group A than in group B. It is possible that the patients in group A had poorer prognoses than those in group B due to the advanced stage of their disease. However, the survival curves for cardiac death in groups A and B were still significantly different after stratification according to the severity of LV systolic dysfunction. Also, the reasons for the use of antiarrhythmics were unclear. It may be possible that the presence of atrial and/or ventricular arrhythmias was associated with poor prognosis in patients with antiarrhythmics, though the incidence of atrial fibrillation at diagnosis was similar between the patients treated with antiarrhythmics and those without.

The results of medical treatment were analyzed on an intention to treat basis (prescribed at diagnosis). Recent non-medical therapies (such as implantable cardioverter defibrillators, bi-ventricular pacing, mitral valve surgery and LV volume reduction) could affect the prognosis in patients with DCM, though no patients were treated with these therapies in the present study. Further studies with a large number of Japanese patients with long-term follow-up are required.
