Background: Arterial repair in the early phase following implantation of a zotarolimus-eluting stent (ZES) remains unknown.

Methods and Results: Following implantation of 49 Endeavor ZES in 33 patients, follow-up angioscopy was performed in 13 patients (26 ZES) in the early phase (EP: 123±24 days) and in 20 patients (23 ZES) in the middle phase (MP: 247±17 days). Neointimal coverage (NIC) was graded as follows: grade 0, stent struts exposed; grade 1, struts bulging into the lumen, although covered; grade 2, struts were embedded by the neointima but were seen translucently; grade 3, struts fully embedded and invisible. NIC was defined as heterogeneous for NIC grade variation ≥1. The presence of thrombus and yellow plaque was also investigated. Although NIC heterogeneity tended to be more frequent in EP than in MP (50% vs. 22%, P=0.070), and yellow plaque significantly more frequent (58% vs. 13%, P=0.0025), the majority of stents were dominant NIC grade 3 at both follow-up periods (73% in EP vs. 78% in MP, P=0.75). There was no significant difference in thrombus (23% in EP vs. 4% in MP, P=0.10) between the follow-ups.

Conclusions: Sufficient arterial repair may have occurred by 4 months after ZES implantation. (Circ J 2013; 77: 1186–1192)

Key Words: Angioscopy; Drug-eluting stent; Imaging; Zotarolimus-eluting stent

D rug-eluting stents (DES) have successfully decreased the rate of in-stent restenosis and target lesion revascularization by inhibiting neointimal proliferation.1 Late stent thrombosis (LST), however, can occur >1 month after DES implantation, causing sudden death or myocardial infarction.2,3 The American College of Cardiology Foundation/American Heart Association/Society for Cardiovascular Angiography and Interventions guideline recommends that dual anti-platelet therapy (DAPT) be continued for at least 1 year to avoid LST.4 Recently, new-generation DES have been developed to overcome the weaknesses of the first-generation DES, but there is as yet insufficient evidence to revise the guideline. Among the new-generation DES, zotarolimus-eluting stents (ZES; Endeavor, Medtronic, Minneapolis, MN, USA) have higher late lumen loss than other DES,5,6 suggesting that arterial repair occurs earlier with ZES than other DES. The arterial repair in the early phase following ZES implantation, however, remains unclear.

Angioscopy directly visualizes arterial healing following stenting.7–23 In our previous study, ZES had adequate neointimal coverage (NIC) on angioscopy at 8 months after stent implantation.8 In the present study, we used angiography to examine the earlier phase of arterial repair following ZES implantation.

Methods

Patients
This study examined 49 ZES placed in 33 patients (age 67±11 years, male 79%) presenting with stable angina pectoris due to de novo lesions in the native coronary arteries. Of these, 20 consecutive patients (23 ZES) received follow-up angioscopy as well as angiography at approximately 8 months after stent implantation (8±1 months: middle phase group [MP]). After the series, we compared the angioscopic findings with those of 13 consecutive patients (26 ZES) taken at approximately 4 months after implantation (4±1 months: early phase group [EP]). At the time of the initial hospitalization to receive ZES implantation, the follow-up catheterizations were scheduled for all patients. All patients received ticlopidine (200 mg/day) or clopidogrel (75 mg/day) in addition to aspirin (100 mg/day) during the follow-up. Glycoprotein IIb/IIIa inhibitors were not
Arterial Repair 4 Months After ZES Implantation

Angioscopy images were analyzed to determine the following: (1) dominant degree of NIC over the stent; (2) heterogeneity of NIC; (3) existence and extent of exposed struts; (4) existence of thrombus; and (5) existence of yellow plaque (YP) underneath the stent. NIC over the stent was classified into 4 grades as previously described: grade 0, stent struts fully visible, similar to immediately after implantation; grade 1, stent struts bulged into the lumen and, although covered, were still transparently visible; grade 2, stent struts were embedded by the neointima but were seen translucently; grade 3, stent struts fully embedded and invisible on angioscopy. Heterogeneity of NIC was defined as in our previous study.

NIC was evaluated in the entire stented segments, and NIC was judged as heterogeneous when one or more differences in NIC grade were apparent. Struts that crossed the side branch were excluded from grading. The stent edges were also excluded from the heterogeneity analysis. Overlapping stent segments were evaluated separately. Existence and extent of the exposed struts were scored as follows: exposure (exp) 0, no NIC grade 0; exp 1, NIC grade 0 in limited areas; exp 2, NIC grade 0 ≤30% of stent surface area; exp 3, NIC grade 0 ≥30%, but not completely exposed; exp 4, struts completely exposed. Thrombus was defined based on the criteria adopted by the European Working Group on Coronary Angioscopy.

The angioscopic definition of YP was adopted from earlier reports.

Angiographic and Angioscopic Follow-up
Coronary angiography (CAG) was performed after unfractionated heparin (5,000 IU) was given into the radial or femoral artery via the inserted sheath, and isosorbide dinitrate (2.5 mg) into the coronary artery. Angioscopy was subsequently performed using a Vecmova NEO angioscope catheter (FiberTech, Tokyo, Japan), the detailed specifications and usage of which have been described elsewhere. Briefly, the optical fiber was placed at the distal segment of the coronary artery and was manually pulled back from the distal edge of the stent to the proximal edge under careful angioscopic and angiographic guidance. Angioscopic images consisted of 3,000 pixels with full color and were stored on digital videotape for off-line analysis.

Quantitative CAG (QCA)
CAG was performed in at least 10 projections, and the view showing the most severe stenosis was selected for QCA. QCA was then performed using a computerized angiographic analysis system (Pie Medical BV, Maastricht, the Netherlands) at the same angle of projection before stenting, immediately after stenting, and at follow-up.

Data given as mean±SD (median) or n (%). †Based on the American College of Cardiology/American Heart Association classification.
Intervention assessment. Minimum lumen diameter tended to be smaller in the EP group at post-intervention assessment, but not significantly so. At follow-up, there were no significant differences between the groups. There was little difference in in-stent late loss from before intervention to follow-up between the EP and MP groups (0.54 ± 0.39 mm vs. 0.59 ± 0.22 mm, P=0.25).

Angioscopic Findings
Dominant NIC grade was either grade 2 or grade 3 in all stents and did not significantly differ between the groups (Figure 1). A representative case is shown in Figure 2. There was a trend toward more heterogeneous NIC in the EP group (Figure 3, P=0.070). Stent exposure grade was significantly different between the 2 groups (P=0.026, Figure 4); the majority of stents were exp 0 in the MP group, whereas stents in the EP group were distributed from exp 0 to exp 3. Nonetheless, widely exposed struts (> exp 3) were rarely observed in either the EP (8%) or MP (0%; P=0.49) group. Existence of thrombus and YP is shown in Figure 5. All the thrombi detected on angioscopy were mural, subclinical, red, and associated with a site of NIC grade 0 or 1. Thrombus was found in 6 patients (23%).

Statistical Analysis
All results are expressed as mean ± SD (median) unless otherwise stated. Groups were compared using the Wilcoxon rank sum test. Categorical variables were analyzed with Fisher’s exact test for 2×2 comparisons; the chi-square test was used for more than 2×2 comparisons. Statistical significance was defined as P<0.05. All calculations were performed using JMP 8.0 (SAS Institute, Cary, NC, USA).

Results
Patients
Patient characteristics were equally distributed between the EP and MP groups (Table 1). Lesion and procedural characteristics are given in Table 2. In terms of lesion characteristics, distribution of the target vessel differed between the 2 groups (P=0.036). There were no differences in procedural characteristics between the groups.

QCA
The QCA findings are listed in Table 3. The data showed no statistical differences between the EP and MP groups at pre-intervention assessment. Minimum lumen diameter tended to be smaller in the EP group at post-intervention assessment, but not significantly so. At follow-up, there were no significant differences between the groups. There was little difference in in-stent late loss from before intervention to follow-up between the EP and MP groups (0.54 ± 0.39 mm vs. 0.59 ± 0.22 mm, P=0.25).

Angioscopic Findings
Dominant NIC grade was either grade 2 or grade 3 in all stents and did not significantly differ between the groups (Figure 1). A representative case is shown in Figure 2. There was a trend toward more heterogeneous NIC in the EP group (Figure 3, P=0.070). Stent exposure grade was significantly different between the 2 groups (P=0.026, Figure 4); the majority of stents were exp 0 in the MP group, whereas stents in the EP group were distributed from exp 0 to exp 3. Nonetheless, widely exposed struts (> exp 3) were rarely observed in either the EP (8%) or MP (0%; P=0.49) group. Existence of thrombus and YP is shown in Figure 5. All the thrombi detected on angioscopy were mural, subclinical, red, and associated with a site of NIC grade 0 or 1. Thrombus was found in 6 patients (23%).
in the EP group and in only 1 patient (4%) in the MP group, although the difference did not reach statistical significance. YP were more frequently observed in the EP group (58%) than in the MP group (13%; P=0.0025).

**Discussion**

The main findings of this study were 3-fold. First, dominant NIC grade ranged from grade 2 to grade 3 in all ZES, and distribution of the dominant NIC grade did not differ between the
Covered by neointima at least 3 months after ZES implantation.

Although the present methodology differed from these 2 studies, NIC following ZES implantation was similar in the present study. Although there are no reports on the relationship between neointimal thickness and re-endothelialization as determined with OCT, previous angioscopic studies have found no thrombus adhesion at the site of NIC grade 2 or 3, suggesting that re-endothelialization was adequate at these locations.

EP and MP groups. Second, widely exposed struts (≥exp 3) were rarely observed in either group. Last, YP were more frequently observed in the EP group.

Using angioscopy, we previously found that after sirolimus-eluting stent (SES, Cypher, Cordis, Miami, FL, USA) implantation the dominant NIC grade tended to be grade 1 at 3–24 months. In contrast, Kim et al reported that on optical coherence tomography (OCT), 99.9% of the stent struts were covered by neointima at least 3 months after ZES implantation. Although the present methodology differed from these 2 studies, NIC following ZES implantation was similar in the present study. Although there are no reports on the relationship between neointimal thickness and re-endothelialization as determined with OCT, previous angioscopic studies have found no thrombus adhesion at the site of NIC grade 2 or 3, suggesting that re-endothelialization was adequate at these locations.
sites.\(^9,11,13\) In contrast to SES, arterial repair may have substantially been achieved as early as 4 months after ZES implantation because dominant NIC grade ranged from grade 2 to 3.

Subclinical thrombus was detected in 23% of struts in EP, and in only 4% in MP. According to the pathological report, thrombus adhesion to the vessel wall/stent strut was an initial phase of neointimal formation.\(^9,11\) ZES in the EP is thought to be still in the process of arterial repair because it had the higher tendency of thrombus adhesion than ZES in the MP.

Angioscopically detected YP is considered to be a vulnerable plaque based on the following observations: in one study, angioscopy and OCT showed that as the fibrous cap became thinner, the yellow tone of the plaque became more intense and as the cap became thicker, the color of the plaque tended to whiten;\(^16,17\) in another study OCT also showed that patients with a thin fibrous cap were prone to acute coronary syndrome (ACS);\(^28\) and plaque ruptures were angioscopically detected within YP in patients with ACS.\(^18\) In contrast, angioscopy showed that YP was covered by white neointima 6 months after bare-metal stent implantation.\(^19\) Although the present patients had stable angina pectoris, given the trend toward heterogeneity 4 months after DES implantation, NIC over YP had not been completed by that time and arterial repair was still ongoing.

**Clinical Implications**

It is currently recommended that DAPT be continued for at least 1 year after DES implantation,\(^4\) but DAPT can cause severe side-effects in some patients. Severe bleeding events occurred in 3.0% of patients who had undergone percutaneous coronary intervention within 1 year after stenting.\(^29\) In addition, the bleeding event rate has been reported to be higher in patients on the triple anti-thrombotic therapy of aspirin, clopidogrel, and warfarin than in those without warfarin, and DES implantation is sometimes necessary in patients who have already been on warfarin.\(^30,31\) Tolerance to DAPT must also be considered. Even with clopidogrel, 4.6% of patients had to discontinue DAPT within 1 month due to several side-effects in addition to bleeding complication.\(^32\) Accidental premature discontinuation of anti-platelet drugs is also considered to be a high risk for LST.\(^33,34\) Under these circumstances, after DES implantation it is favorable to switch from DAPT to mono-antiplatelet therapy as soon as arterial healing is complete.

In our previous angioscopy studies the dominant NIC grade tended to be grade 1 at 3–24 months after SES implantation, which suggests incomplete re-endothelialization.\(^9,11,13\) Observational studies, however, have found no increase in adverse events even when DAPT was switched to monotherapy 6 or 12 months after stenting with SES.\(^33,34\) Taking these findings together, mono-antiplatelet therapy may be sufficient to prevent stent thrombosis in DES with dominant NIC grade ≥1 even if re-endothelialization is incomplete. In the present study, the dominant NIC grade of all ZES was grade 2 or 3 as early as 4 months after implantation although some of the struts were grade 1 due to heterogeneity. It appears then that the risk of stent thrombosis may be low even if NIC grade 1 is partly present.

Pathology showed that when the ratio of uncovered struts to total stent struts per section was >30%, this was a risk factor for stent thrombosis.\(^37\) In the present study, only 8% of the struts had such a ratio in EP. Accordingly, although multiple factors are associated with stent thrombosis, the risk of stent thrombosis at 4 months after ZES implantation might be low even if DAPT is switched to mono-antiplatelet therapy.\(^38\)

**Study Limitations**

This study has several important limitations. First, angioscopy was not performed serially in the same patients after stent implantation, although the patient characteristics did not differ significantly between the EP and MP groups. Second, distribution of the target vessel was significantly different between the groups. Nonetheless, the difference may have little impact on NIC because QCA data, stent size, and stent length were not different between the groups. Third, although serial angioscopy observations are necessary to evaluate the chronological changes in the plaque color, it is impossible because we have no angioscopic data relating to immediately after the stent implantation. Fourth, although we explored intra-stent surfaces of Endeavor ZES, a new version of the ZES (Resolute Integrity ZES; Medtronic), is now available in the clinical setting. We cannot directly extrapolate the present results to the new ZES. Fifth, although angioscopy provides a wide-angle view, anatomical structures, such as tortuous vessels, may disturb the complete circumferential view, which may lead to the missing of small regions. Angioscopic evaluation of NIC on the stent surface remains qualitative. Nonetheless, angioscopy is a robust tool to detect the thrombus. Finally, this study involved a single-center, small sample, and carried out non-randomized observation of intrastent surfaces by angioscopy. In order to elucidate the optimal duration of DAPT, a large-scale, randomized control study is warranted. Analysis across 5 registration trials showed that ZES with DAPT over 6 months did not increase clinical events including stent thrombosis in comparison with DAPT over ≥12 months. Recently, the RESET study verified our hypothesis.\(^39\)

**Conclusions**

Although ZES-implanted lesions were still in the process of arterial repair at 4 months after stenting, the majority of the struts were covered by the neointima; exposed struts as well as thrombus adhesion were rarely observed at this time. Sufficient arterial repair may have occurred by 4 months after ZES stenting.
