Figure 1. (A,B) Three-dimensional (A) streamline and (B) pathline visualization of blood flow during systole in the pulmonary artery (PA) in a pulmonary arterial hypertension (PAH) patient. (C,D) For comparison, 3-D streamline in a healthy volunteer is also shown (C, streamline; D, pathline). White arrows, vortex blood flow; blue, 0 mm/s; red, maximum blood velocity. (E,F) Main PA antegrade and retrograde flow during (E) early and (F) late systole. White arrow, early systolic retrograde flow corresponding to the dorsal side of the PA; yellow arrow, end-systolic retrograde flow that occurred with pulmonary valve closure. LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.
A 16-year-old woman presented to a local city hospital for evaluation of shortness of breath and electrocardiographic abnormality. Twelve-lead electrocardiogram (ECG), lung perfusion scintigraphy and right heart catheterization supported the diagnosis of idiopathic pulmonary arterial hypertension (PAH). After discussion with her cardiologist, she consulted Hamamatsu University Hospital for further treatment. She had World Health Organization functional assessment classification class II symptoms of dyspnea on effort. Cardiac auscultation indicated a III/VI tricuspid regurgitation (TR) murmur and a loud P2 component of S2 heart sound. ECG showed normal sinus rhythm with right-axis deviation, complete right bundle branch block and right ventricular hypertrophy. Echocardiography showed right ventricular hypertrophy without dilatation (right ventricular diameter, 34.9 mm measured on apical 4-chamber view), severe TR with high right ventricle systolic pressure 105 mmHg (estimated using TR pressure gradient), but normal left ventricular function (left ventricular ejection fraction, 79.7%). Cardiac catheterization measurements included mean pulmonary artery (PA) pressure (84 mmHg; 125/57 mmHg), mean right atrial pressure (10 mmHg), mean pulmonary capillary wedge pressure (13 mmHg), and cardiac output (7.75 L/min; cardiac index, 5.11 L·min⁻¹·m⁻² determined on thermodilution).

To further characterize the patient’s pulmonary arterial hemodynamics, gadolinium-enhanced magnetic resonance angiography and phase-resolved 3-dimensional (3-D) phase-contrast magnetic resonance imaging (MRI; 4D-flow) of the PA was done. These techniques allow non-invasive identification of blood flow patterns, measurement of blood flow velocities and wall shear stress (WSS) at each cardiac phase. Whole heart 3-D MRI showed dilatation of the PA. The 3-D streamline (Figure 1A; Movie S1) and pathline (Figure 1B) images clearly demonstrated the existence of vortex blood flow in the main PA, whereas this blood flow pattern was not seen in a healthy volunteer (Figures 1C, D). The duration of vortex was 0.27 s (30.0% of the cardiac cycle). Maximum and mean blood flow velocities at the main PA were 0.45 m/s and 0.07 m/s, respectively. Cross-sectional flow analysis indicated biphasic retrograde flow in the main PA (Figures 1E, F). The location of the early systolic retrograde flow corresponded to the dorsal side of the PA. Three-dimensional surface analysis indicated that the WSS was spatially and temporally heterogeneous (Figures 2A, B; Movie S2) compared with a healthy volunteer (Figures 2C, D). Maximum and mean WSS at the central PA were 0.95 Pa and 0.44 Pa, respectively.

In PAH, cardiac MRI is a useful method for assessing right ventricular function. Right ventricular volume parameters obtained on cardiac MRI are predictors of hospitalization and mortality. Phase-contrast cardiac MRI can also be used to evaluate blood flow volumes and velocities, and visualize blood flow patterns. Previous studies have shown that PA blood flow pattern in PAH patients differs from that in non-PAH participants. The vortex blood flow appearance and the early onset of retrograde flow in main PA are believed to be characteristic of PAH. The duration of vortex is closely related to the mean PA pressure. It was reported that WSS in PAH patients is significantly decreased, which might be a parameter that reflects the progression of the disease. WSS is decreased...
when abnormal flow dynamics such as vortex or turbulent flow occur adjacent to the arterial wall.\(^7\),\(^8\) Therefore, low WSS on the PA wall reflects abnormal hemodynamics occurring within the PA. Previous investigators also reported that the decreased WSS inhibited nitric oxide release from the endothelium.\(^8\)–\(^11\) Color-coded 3-D WSS readily demonstrates PA flow abnormalities and resultant decreased WSS on the PA in a time-resolved and quantitative fashion. Abnormal hemodynamics may also be shown on streamline analysis, but only qualitatively. The present report shows that 4D-flow is a useful non-invasive method for the qualitative and quantitative characterization of not only blood flow but also WSS in PAH patients.
