Optical coherence tomography (OCT) provides high-resolution cross-sectional images to evaluate vessel healing in response to stent placement. Using OCT, a recent study reported the association between late stent thrombosis and the percentage of uncovered struts measured by OCT. This suggests that findings such as uncovered struts assessed by mid-term OCT could be a potential surrogate for the risk assessment of future stent thrombosis.

Although guidelines recommend at least 12 months of dual antiplatelet therapy (DAPT) after DES implantation, several studies suggest that 6-month DAPT is safe and does not compromise the efficacy of the stent. However, there is a limited notion of vessel healing at this time point and the 6-month OCT data is crucial for understanding the long-term effects of these stents.

32 patients were enrolled in the study (Figure 1), which was approved by the Ethics Committee of Kobe University, and all enrolled patients gave written informed consent.

Quantitative Coronary Angiography Analysis
Coronary angiograms obtained at baseline and at 6- and 12-month follow-ups were analyzed using a computer-based system using edge-detection techniques (QCA-CMS5.1, Medis Imaging Systems, Leiden, The Netherlands) by investigators masked to the clinical presentation, lesion characteristics, and stent assignment. The quantitative angiographic parameters included: (1) minimal lumen diameter (MLD), (2) reference vessel diameter, (3) percent diameter stenosis, (4) late loss, and (5) delayed late loss. Late loss was defined as the difference between the MLD after the procedure and that at the 6-month follow-up. Delayed late loss was defined as the difference between the MLDs at the 6- and 12-month follow-ups.

OCT Examination
OCT examination was serially performed 6 and 12 months after stenting. Frequency-domain OCT was used as previously reported. Briefly, a 0.014-inch standard guide wire was positioned distally in the target vessel, and the frequency-domain OCT catheter (C7 Dragonfly™, St. Jude Medical, St. Paul, MN, USA) was advanced to the distal end of the target lesion. The entire length of the region of interest was scanned using the integrated automated pullback device at 20 mm/s. For image acquisition, blood in the coronary artery was replaced with iodine contrast media continuously flushed using a power injector, in order to create a virtually blood-free environment. The volume and infusion flow rate were decided by the operator and ranged from 8–20 cm³ at 3–7 cm³/s and 400 pounds per square inch.

Methods
Study Population
In this prospective observational cohort study, a total of 32 patients treated with BES (Terumo Corporation, Tokyo, Japan) were consecutively enrolled from April 2011 to March 2012. Patients aged over 18 years and eligible for percutaneous coronary intervention (PCI) were included. The index PCI procedure was performed with intravascular ultrasound guidance using a mechanical ultrasound transducer (Boston Scientific Corporation, Natick, MA, USA) or a dynamic-aperture ultrasound transducer (Volcano Corporation, Rancho Cordova, CA, USA). All patients were recommended to take DAPT comprising aspirin 100 mg/day and clopidogrel 75 mg/day for at least 12 months after BES implantation. The exclusion criteria were serious hepatic or renal dysfunction, target lesion in a saphenous vein graft and in-stent restenosis, target lesion revascularization during follow-up, unavailable for repeat coronary angiogram because of renal dysfunction, and discontinuation of DAPT at 6 months. Eventually, 37 BES-treated lesions in 32 patients were enrolled in the study (Figure 1), which was approved by the Ethics Committee of Kobe University, and all enrolled patients gave written informed consent.

Quantitative Coronary Angiography Analysis
Coronary angiograms obtained at baseline and at 6- and 12-month follow-ups were analyzed using a computer-based system using edge-detection techniques (QCA-CMS5.1, Medis Imaging Systems, Leiden, The Netherlands) by investigators masked to the clinical presentation, lesion characteristics, and stent assignment. The quantitative angiographic parameters included: (1) minimal lumen diameter (MLD), (2) reference vessel diameter, (3) percent diameter stenosis, (4) late loss, and (5) delayed late loss. Late loss was defined as the difference between the MLD after the procedure and that at the 6-month follow-up. Delayed late loss was defined as the difference between the MLDs at the 6- and 12-month follow-ups.
OCT Analysis

Off-line OCT analysis was performed using the dedicated software (LightLab Imaging Inc, Westford, MA, USA). All images were analyzed by independent observers masked to the clinical presentation, lesion characteristics, and stent assignment. For quantitative analysis, cross-sectional OCT images were analyzed at 1-mm intervals. For the image matching, we used the distance from the stent edge and landmarks such as side branches to match the location of the cross-sections in the 6- and 12-month examinations. Struts were classified as uncovered if any part of the strut was visibly exposed to the lumen, or as covered if a layer of tissue was visible over all the reflecting surfaces. Neointimal thickness was measured from the center reflection of the stent strut to the vessel-lumen border (neointimal surface or strut surface if uncovered) for each stent strut. An uncovered strut was defined as a strut with a neointimal thickness equal to 0 μm. The frequency of covered and uncovered struts was calculated as the number of those struts divided by the total number of struts for each stent. To assess for asymmetric stent expansion, a stent eccentricity index was determined by the minimum stent diameter divided by the maximum stent diameter in each cross-section. For assessing the unevenness of neointimal thickness, a neointimal unevenness score (NUS) was calculated for each cross-section as the maximum neointimal thickness in 1 cross-section divided by the average neointimal thickness of the same cross-section. A malapposed strut was defined as a distance ≥140 μm between the center reflection of the strut to the vessel wall. This criterion was determined by adding the actual strut thickness (125 μm), Parylene C (which is not an absorbable polymer) thickness (10 μm) and absorbable polymer thickness (15 μm) at 0 day, 3 μm at 6 months (data on file of Terumo corporation), 0 μm at 12 months) to the OCT resolution limit (6 months: 125 ± 10 + 3 μm = 138 μm, 12 months: 125 + 10 + 0 μm = 135 μm). The frequencies of stents with a peri-strut low-intensity area (PLIA) or with an extra-stent lumen (ESL) were calculated. The incidence of stents with PLIA was calculated on a per-stent basis of any strut with PLIA. PLIA was defined as the region around stent struts that homogeneously had lower intensity than the surrounding tissue on OCT images and did not have significant signal attenuation behind the area, suggestive of fibrin deposition or impaired neointima maturation. If a cross-section had a lumen outside the stent, the lumen was defined as ESL. Both the lumen of malapposed struts and the excavated lumen without malapposed struts were included as ESL. Stent and lumen area were measured manually, and neointimal area was calculated as stent area plus ESL area minus lumen area.

The frequency of stents with atherogenic neointima (AN) or with in-stent thrombi was calculated. AN was defined as neointima containing a diffuse border and poor-signal region with invisible struts underneath because of marked signal attenuation. Layered morphology such as high abluminal and low adluminal layers with visible strut was not defined as AN. In-stent thrombi were defined as a mass protruding beyond the stent strut into the lumen with significant attenuation behind the mass. The presence of stent with PLIA, ESL, AN, and in-stent thrombi required the agreement of 2 independent experienced observers. Representative images of cases of PLIA, ESL, and in-stent thrombi are shown in Figure 2.

Clinical Events

Clinical outcome data (>12 months) were obtained from outpatient record reviews or telephone interviews of 30 patients. Cardiac death, myocardial infarction (MI: defined according to the World Health Organization definition using creatine kinase and creatine kinase-MB increases),19 target lesion revascularization [(TLR) and target vessel revascularization (TVR) both defined as the need for a repeat PCI], stent thrombosis according to ARC definition,20 and the composite endpoint of major adverse cardiac events (cardiac death, MI, stent thrombosis, TLR) were evaluated. Although OCT images were not always available because of quality in patients with adverse cardiac events, they were evaluated for the entire study population (Figure 1).

Statistical Analysis

Statistical analysis was conducted using a commercially available SPSS software version 16.0 (SPSS Inc, Chicago, IL, USA). Qualitative data are presented with frequencies, and quantitative data are shown as mean±SD. For continuous variables, comparisons between 2 groups were performed using a 2-tailed, paired t-test, or Wilcoxon test. Discrete variables are presented as percentages, and comparisons were performed using the
between the OCT cohort and the entire study population (Table 1). In the OCT cohort, the mean duration from BES implantation to the 6- and the 12-month follow-ups were 6.5±0.5 months and 12.4±0.4 months, respectively. The 26 BES were implanted in patients with stable angina (91%), acute coronary syndrome (1 patient, 4.3%), and acute MI (1 patient, 4.3%). The 23 patients (100%) continued DAPT with aspirin 100 mg/day and clopidogrel 75 mg/day up to the 6-month follow-up, and 18 (78.2%) continued it to the 12-month follow-up; 5 patients ceased DAPT at 6 months by clinic physicians’ discretion with the patients’ consent.

### Results

#### Baseline Patient and Lesion Characteristics

There were 2 patients lost to follow-up, and 7 patients were excluded for various reasons (Figure 1), so a total number of 23 patients with 28 lesions prospectively underwent serial OCT at 6 and 12 months.

Baseline patient and lesion characteristics were well matched between the OCT cohort and the entire study population (Table 1). In the OCT cohort, the mean duration from BES implantation to the 6- and the 12-month follow-ups were 6.5±0.5 months and 12.4±0.4 months, respectively. The 26 BES were implanted in patients with stable angina (91%), acute coronary syndrome (1 patient, 4.3%), and acute MI (1 patient, 4.3%). The 23 patients (100%) continued DAPT with aspirin 100 mg/day and clopidogrel 75 mg/day up to the 6-month follow-up, and 18 (78.2%) continued it to the 12-month follow-up; 5 patients ceased DAPT at 6 months by clinic physicians’ discretion with the patients’ consent.
Angiographic Analysis

Angiographic results of the OCT cohort at the pre-intervention, post-intervention, 6- and 12-month follow-ups are shown in Table 2. In-stent MLD showed no significant change from 2.62±0.52 mm at the 6-month follow-up to 2.59±0.46 mm at the 12-month follow-up (P=0.60). In-stent late loss was 0.08±0.36 mm, and in-stent delayed late loss was 0.02±0.31 mm.

OCT Analysis

A total of 600 matched cross-sections were analyzed (Table 3). The average neointimal thickness was 72±23 μm at the 6-month follow-up and 82±25 μm at the 12-month follow-up. There was a significant, but small increase in neointimal thickness (P=0.006) from the 6- to the 12-month follow-up. The average lumen area (6.67±2.04 mm² to 6.47±2.04 mm²; P=0.12) and the average minimum lumen area (5.11±2.24 mm² to 4.95±2.06 mm²; P=0.30) did not significantly change from the 6-month to the 12-month follow-up. Average NUS significantly changed from the 6- to the 12-month follow-up (1.99±0.21 vs. 1.89±0.21; P=0.01) (Table 3).

The incidences of uncovered and malapposed struts were low at the 6-month follow-up, and further reduced at the 12-month follow-up (3.96±3.97% to 1.51±1.63%; P=0.001 and 0.50±1.84% to 0.06±0.24%; P=0.20, respectively). Contrarily, although the incidence of stents with completely covered struts was only 10% at the 6-month follow-up, it had increased to 28% at the 12-month follow-up (P=0.09).

The percentage of stents with PLIA and that with in-stent thrombi decreased from the 6- to the 12-month follow-up (Table 3). Only 2 stents had attached thrombi at the 6-month follow-up, and these were completely resolved by the 12-month follow-up. The frequency of stents with ESL decreased from the 6- to the 12-month follow-up (53% to 46%; P=0.37). AN was not observed in either phase. Representative OCT images of the 6- and the 12-month follow-ups are shown in Figure 3.

In this study, 5 patients did not take clopidogrel after the 6-month OCT examination, so we analyzed the 12-month OCT findings between the 6- and 12-month DAPT. There was no significant difference in strut coverage at 12-month OCT between the 6- and 12-month DAPT (mean neointimal thickness: 6-month DAPT 80±23 μm vs. 12-month DAPT 82±26 μm, P=0.86) (frequency of uncovered struts: 6-month DAPT 1.22±1.37% vs. 12-month DAPT 1.57±1.70%, P=0.67) (frequency of malapposed struts: 6-month DAPT 0.00±0.00% vs. 12-month DAPT 0.08±0.23%, P=0.51) (frequency of stent with 100% covered struts: 6-month DAPT 40% vs. 12-month DAPT 26%, P=0.55) (Table 4).

Clinical Events

Clinical outcome data for >12 months were available for 30 patients (Table 5); 2 patients required TLR and TVR (6.7%) 6.3±0.3 months after BES deployment. There were no cardiac-related deaths, MI, or stent thrombosis after BES implantation. Thus, the incidence of major adverse cardiac events was 6.7% during the 12-month follow-up.

Discussion

We evaluated the time course of arterial healing after BES implantation using matched, serial OCT at 6 and 12 months in patients with coronary artery disease. The major findings of the present study are as follows. (1) The OCT findings at 6 months revealed that BES had a low percentage of uncovered and malapposed struts, and from the 6- to the 12-month follow-up there was further strut coverage. (2) There was a small increase in neointimal thickness from 6 to 12 months, and this neointimal growth did not compromise the lumen area within the stent. (3) AN was not detected by OCT imaging.

Qualitative and Quantitative OCT Assessment After BES Implantation

Recent reports have concluded that delayed arterial healing because of uncovered struts, malapposed struts, in-stent thrombi, and PLIA is associated with in-stent restenosis. Furthermore, a greater percentage of uncovered struts is associated with the incidence of stent thrombosis. In a previous study, the 6-month OCT findings after paclitaxel-eluting stent (PES) implantation revealed that the frequency of uncovered struts, malapposed struts, and that of stent with in-stent thrombi was 5.2%, 1.9%, and 47%, respectively.

In contrast, our study results showed that for BES the frequency of uncovered struts, malapposed struts and that of stent

An emerging challenge in DES treatment is the shortened DAPT duration. Possibility for Shortening the Duration of DAPT

Second-generation DES such as everolimus-eluting stent (EES) have a more favorable healing profile, which has been associated with a lower incidence of late stent thrombosis compared with first-generation DES. Recently, Puricel et al reported that at 2 years the frequency of stent thrombosis after BES implantation is equal to that after EES implantation. According to the Japanese Circulation Society guidelines, DAPT after BES implantation is equal to that after EES implantation. The kinetics of drug release may affect the mid-term strut coverage. A recent study revealed that in a 9-month OCT analysis of BES and SES, the average tissue thickness was 67 µm in vessels implanted with BES and 57 µm in those implanted with SES (P=0.19). Therefore, mid-term neointimal suppression after BES implantation was as good as that after SES implantation. The elution period for BES is 6–9 months, which is longer than for EES or SES. In a recent study, the neointimal thickness was 80 µm in EES at 6 months, which is as good as that with BES in the present study. The frequency of stents with in-stent thrombi with EES was 19%, which is higher than that with BES. However, from the clinical evidence as of now, the duration of DAPT should not be decided only from imaging results. Further study is warranted to prospectively assess the effect of the OCT findings on clinical outcome after cessation of DAPT.

In the present study, 5 patients with BES did not take clopidogrel after the 6-month OCT examination. We compared the 12-month OCT findings between 6- and 12-months of DAPT. There was no significant difference in strut coverage at 12-month OCT between the 6- and 12-month DAPT groups. Further randomized clinical trials comparing vessel healing between 6-month and prolonged DAPT are warranted.

**Vascular Reactions and Vessel Healing After BES Implantation**

BES are coated on the abluminal side only with a biodegradable polymer that degrades over the 6–9 months after stent deployment. Although biodegradability, in part, may reduce the long-term adverse reactions of durable polymers, there is a theoretical risk of polymer degradation-induced adverse vessel reaction. In fact, Willen et al reported that in a porcine model an array of biodegradable polymers can induce marked inflammatory reactions within coronary arteries and subsequent neointimal thickening. However, serial in-vivo assessment of vascular responses during polymer degradation period has not been performed. In the present study, the average neointimal thickness was 72 µm in 6 months. Additionally, there was a small increase in neointimal thickness from the 6- to the 12-month follow-up.

Using OCT, a recent study reported an association between the percentage of uncovered struts measured by mid-term OCT and subsequent occurrence of late and very late stent thrombosis. Given the association between late stent thrombosis and the percentage of uncovered struts measured by OCT, it is rational to measure these parameters when physicians are considering cessation of DAPT. The few reports of 6-month OCT examination with EES have revealed that the frequency of uncovered struts and malapposed struts is 2.3% and 2.1%, respectively, which is as good as that with BES in the present study. The frequency of stents with in-stent thrombi with EES was 19%, which is higher than that with BES. However, from the clinical evidence as of now, the duration of DAPT should not be decided only from imaging results. Further study is warranted to prospectively assess the effect of the OCT findings on clinical outcome after cessation of DAPT.

In the present study, 5 patients with BES did not take clopidogrel after the 6-month OCT examination. We compared the 12-month OCT findings between 6- and 12-months of DAPT. There was no significant difference in strut coverage at 12-month OCT between the 6- and 12-month DAPT groups. Further randomized clinical trials comparing vessel healing between 6-month and prolonged DAPT are warranted.

with in-stent thrombi was 3.96%, 0.5% and 7.0%, respectively. BES had stabilized in the 6-month OCT findings. Progressive vessel healing was observed in lesions from 6 to 12 months after BES implantation. Therefore, we consider BES is safer than first-generation DES at the 1-year follow-up.

Furthermore, the percentage of stent with PLIA decreased from the 6- to the 12-month follow-up. PLIA is suggestive of fibrin deposition or premature neointima with inflammatory cell infiltration, which is often observed in the healing process. In most cases, fibrin deposition is replaced by smooth muscle cell following disappearance of inflammation around the stent struts. As a result, when OCT-based morphology was serially assessed, PLIA was replaced by highly homogeneous neointima from the 6- to the 12-month imaging. Additionally, in other DES neointimal hyperplasia is observed during this healing process; whereas, despite the decrease of PLIA, BES showed minimal neointimal growth from 6 to 12 months, suggesting benign polymer degradation and slow-release kinetics of biolimus A9.
as that in BES. However, in another study, the average neo-
intimal thickness with EES at 12 months was 97 µm, 33 which
is thicker than that with BES. Moreover, another study revealed
that the mean thickness of coverage was 142 µm at 13 months
after EES implantation. 33 Furthermore, we reported that the
average neo-intimal thickness with EES was 72 µm at 6 months
and 126 µm at 12 months. 34 Neo-intimal growth from 6 to 12
months after implantation with EES was greater than that with
BES. The slow-release kinetics of biolimus A9 after BES im-
plantation minimized neo-intimal growth from the 6- to the
12-month follow-up. We speculate that the antiinflammatory
and highly lipophilic properties of biolimus A9 may inhibit
polymer degradation-induced inflammatory reactions.
We should also consider adverse vessel reactions at the long-
term follow-up after complete drug release and polymer deg-
radiation. Robert reported that the 2-year repeat angiographic
data indicated that neo-intimal suppression with polymer-free
DES is greater than that with permanent-polymer DES. 35 Per-
sistent inflammatory effect and failure of stent endothelializa-
tion with permanent-polymer DES generates a nidus for plate-
let activation and fibrin deposition that, in turn, initiates the
chemokine cascade leading to neo-intimal hyperplasia. There-
fore, we speculate that neo-intimal suppression may be greater
in a lesion treated with BES than in one treated with perma-
nent-polymer DES such as SES, even at long-term follow-up.

Atherosclerotic Changes in the Neo-intima After BES
Implantation
Neoatherosclerosis is frequently observed after implantation of
first-generation DES and has been reported to occur earlier
with first-generation stents (1.5±0.4 years) than with bare metal
stents (6.1±1.5 years). 36 A recent study revealed that the earli-
est duration of implantation showing neoatherosclerosis with
SES and PES was 120 days and 70 days, respectively. 37 In-
stent neoatherosclerosis, which can be assessed using OCT,
may be an important mechanism for DES failure. 17 In the pre-
sent study, AN was not observed at either follow-up.
Hamilos et al reported that, unlike that in SES, endothelium-
dependent vasomotion at the adjacent stent segment is preserved
after BES implantation. 38 Similarly, Pendyala et al revealed a
significantly lowered inflammatory response in the stented
segments and rapid recovery of endothelial function in persist-
ent segments in the BES group compared with the Cypher
group. 39 We speculate that a lower inflammatory response and
rapid recovery of endothelial function after BES implantation
might protect against atherogenic change. Larger and longer
follow-up studies are warranted to validate our hypothesis.

Study Limitations
This was a single-center, observational study with a small sam-
ple. Additionally, we only examined BES and did not compare
its effect with other DES. Moreover, we enrolled only event-
free patients, which may lead to selection bias. Furthermore,
neoatherosclerosis occurs in lesions much later after DES
implantation. This study shows only mid-term follow-up data.
Therefore, a larger sample population and a longer follow-up
period are warranted.

Conclusions
Neo-intimal hyperplasia was persistently suppressed up to 12
months following BES implantation. Simultaneously, favor-
able vessel healing was achieved at 6 months without a delay-
ing adverse reaction for up to 12 months.

Acknowledgments
The authors thank all the patients who agreed to participate in this study.
