Figure 1. (A) Pre-procedural multislice computed tomography showed significant aortic leaflet calcification. (B) Mid-esophageal 135° transesophageal echocardiography (TEE) view showed severe aortic stenosis and mild mitral thickening with doming of the anterior leaflet, suggestive of rheumatic disease. (C) Mild mitral regurgitation (MR) without significant stenosis was observed. (D) Long-axis TEE view during balloon aortic valvuloplasty under rapid ventricular pacing. (E) Four-chamber view showing a telesystolic frame with absence of coaptation of both mitral valve leaflets, resulting in (F) severe MR. (G) 3-D multiplanar reconstruction of the mitral valve, showing restricted mobility of both leaflets in telesystole, consistent with a functional mechanism of MR.
A 91-year-old woman underwent transcatheter aortic valve implantation (TAVI) for symptomatic severe aortic stenosis (Figure 1A). Baseline transthoracic echocardiography showed a severely calcified aortic valve with a medium pressure gradient of 40.5 mmHg, an estimated orifice area of 0.73 cm², and mildly impaired left ventricular (LV) function. A LV ejection fraction of 50% was calculated using the Simpson biplane method, and there were signs of elevated LV filling pressure (E/E' ratio, 15.7). Pre-procedural evaluation with transesophageal echocardiography (TEE) showed mild mitral valve thickening with doming of the anterior leaflet, consistent with rheumatic valve disease. Mild mitral regurgitation (MR) without significant stenosis was observed (Figures 1B, C). Prior to TAVI placement, balloon aortic valvuloplasty was performed under rapid ventricular pacing (RVP) at 180 beats/min (Figure 1D). Subsequently, also under RVP, a 26-mm balloon-expandable aortic valve (SAPIEN XT, Edwards Lifesciences) was placed. Fluoroscopy and TEE demonstrated optimal valve apposition, without significant paravalvular regurgitation. Nevertheless, the patient had progressive hemodynamic deterioration requiring inotropic support. TEE showed severe biventricular dysfunction and massive MR resulting from restricted systolic motion of both mitral leaflets, leading to incomplete coaptation. Aortic angiography excluded coronary embolization. All wires and catheters were removed from the ventricular cavity in order to rule out any interference with mitral subvalvular apparatus, but severe MR persisted without any change (Figures 1E–G; Movies S1, S2). After several minutes, progressive normalization of LV function took place, and final TEE evaluation confirmed return to baseline situation, with mild MR and normal leaflet coaptation (Figure 2).

Percutaneous aortic valve implantation is an effective and increasingly used technique in patients with severe aortic stenosis.1,2 The present case illustrates the deleterious effects that RVP during TAVI can have on myocardial contractility. In this patient, biventricular dysfunction additionally led to functional massive MR, contributing to the hemodynamic instability. La Paz University Hospital is a level 1 cardiac center, wherein 50–60 TAVI procedures are performed each year, and this is the first patient in whom we have observed this “rapid-pacing induced MR” phenomenon. We believe that LV systolic dysfunction prior to TAVI may be a risk factor for this. Limiting RVP time and selection of optimal pacing sites (ie, right ventricular outflow tract) may prevent the development of this severe complication. This case also highlights the critical role of real-time TEE monitoring, which enables the prompt detection and treatment of periprocedural complications.3
