Vascular Toxicity of Phosphate in Chronic Kidney Disease – Beyond Vascular Calcification –

Priscilla Gross, BSc; Isabelle Six, PhD; Said Kamel, PhD; Ziad A. Massy, MD, PhD

Chronic kidney disease (CKD) is characterized by high cardiovascular morbidity/mortality, which is linked in part to vascular calcification (VC) and endothelial dysfunction (ED). Hyperphosphatemia, a feature of CKD, is a well-known inducer of VC in preclinical models and is associated with poor outcomes in epidemiological studies. However, it remains to be seen whether lowering phosphate levels in CKD patients reduces VC and the morbidity/mortality rate. Furthermore, it is now clear from preclinical and clinical studies that phosphate is involved in ED. The present article reviews the direct and indirect mechanisms (eg, via fibroblast growth factor 23 and/or parathyroid hormone) by which hyperphosphatemia influence the onset of VC and ED in CKD.

Key Words: Endothelial dysfunction; Phosphate; Phosphate-regulating hormones; Vascular calcification

Phosphate, principally provided by food, is involved in many physiological processes: it buffers the intracellular pH, ensures the stability of the skeleton and contributes to many essential biological functions (eg, DNA synthesis, cell membrane phospholipids, energy metabolism and intracellular signaling pathways that are regulated by phosphorylation/dephosphorylation).

The physiological concentration of phosphate (0.8–1.5 mmol/L) is tightly regulated by, among others, the fibroblast growth factor 23 (FGF23)/Klotho axis, parathyroid hormone (PTH) and calcitriol (the active form of vitamin D).1

In chronic kidney disease (CKD), the progressive loss of functional nephrons induces retention of phosphate, which in turn leads to (1) an increase in calcium/phosphate products and (2) FGF23 synthesis. With the aim of preventing hyperphosphatemia, FGF23 decreases circulating levels of calcitriol, thus inhibiting intestinal phosphate and calcium absorption. PTH, the overexpression of which is triggered by hypocalcemia, stimulates bone resorption for the primary purpose of restoring calcium and thus the calcium/phosphate products. During the course of CKD, Klotho’s downregulation in both the parathyroid gland and the kidney results in the loss of FGF23 being able to respectively (1) decrease PTH expression and (2) inhibit renal phosphate reabsorption. In late-stage CKD, the few remaining functional nephrons are no longer able to eliminate phosphate and a vicious circle (referred to as secondary hyperparathyroidism) appears with hyperphosphatemia as the ultimate consequence.2

Patients with CKD are considered to be in the “highest risk group” for cardiovascular (CV) morbidity/mortality.3,4 In epidemiological studies of CKD patients and the general population, high phosphate levels are associated with CV disease (CVD). The association is even observed in early-stage CKD and is independent of other traditional CV risk factors.5,6 Along with other factors, hyperphosphatemia is involved in the development of vascular calcification (VC) and endothelial dysfunction (ED),7–9 both of which are major nontraditional CV risk factors for CKD. Phosphate is able to act either directly on these parameters or indirectly via the FGF23/Klotho and PTH axes (Figure 1).

We review the various effects of hyperphosphatemia on CV parameters, with a focus on its emerging role in ED. The efficacy of current therapies for improving phosphate-related CV outcomes is also discussed.

Direct Effects of Phosphate on CV Calcification and ED

Epidemiological and Interventional Studies
VC is deposition of calcium/phosphate, mostly as apatite, in the blood vessels, myocardium and cardiac valves. Calcification of both the intima and media occurs in CKD,10 resulting in the stiffness of the large arteries (as evidenced by a higher pulse wave velocity) and thus promotion of CV morbidity/mortality.

The results of several epidemiological studies have highlighted an association between serum phosphate levels and VC in stage 5D CKD patients,11,12 in early-stage CKD patients and in the general population (in whom serum phosphate levels are still within the normal range).13,14 Indeed, 2 elegant prospective studies of large cohorts of
healthy adults have demonstrated that phosphorus levels at the upper limit of the normal range are independently associated with a greater likelihood and a more rapid progression of coronary artery calcium.\textsuperscript{14,15} In a study involving 439 multi-ethnic participants with moderate CKD but no clinical signs of CVD, Adeney et al reported that each 1 mg/dL (0.32 mmol/L) increment in phosphate level is strongly (P=0.002) and independently associated with a higher prevalence of calcification.\textsuperscript{13}

Actual therapy to manage hyperphosphatemia in endstage CKD includes, among others, oral phosphate binders such as calcium acetate, sevelamer or lanthanum. The published results of randomized controlled trials (RCTs) have not clearly established whether normalizing serum phosphate levels reduces VC and/or affects survival.\textsuperscript{16,17} The first RCT (conducted by Chertow et al on 200 hemodialysis patients) found that after 52 weeks of follow-up, patients receiving calcium acetate displayed higher calcium scores for the coronary arteries and thoracic aorta than those treated with sevelamer.\textsuperscript{18} In contrast, the BRIC study involving 101 hemodialysis patients failed to observe a beneficial effect of lowering serum phosphate levels on progression of coronary artery calcium after a 12-week follow-up period.\textsuperscript{19} Similar results were reported by Qunibi et al on a larger cohort of hemodialysis patients monitored over a 12-month period.\textsuperscript{20}

More recently, a pilot RCT looked at the VC risks and benefits associated with the use of phosphate binders in early-stage CKD.\textsuperscript{21} Although phosphate binders effectively lowered serum and urinary phosphate levels in patients not yet on dialysis, methodological problems prevented the researchers from drawing firm conclusions regarding VC.\textsuperscript{21}

Compared with healthy people, CKD patients have impairments in endothelium-dependent relaxation, emphasizing the endothelium’s essential role in CKD.\textsuperscript{22} Recent data have evidenced a relationship between ED and VC, with the first appearing earlier during the course of CKD.\textsuperscript{23} Both these factors contribute to arterial stiffness, left ventricular hypertrophy and ultimately heart failure, the major cause of death in CKD patients. It remains to be determined whether managing the ED can delay VC and affect CV mortality.

Shuto et al\textsuperscript{24} provided the first in vivo evidence of a direct contribution of phosphate to the onset of ED. They measured the flow-mediated dilation (FMD) of the brachial artery (as an indicator of endothelial function) in 11 healthy subjects who had been provided meals containing either 400 mg or 1,200 mg of phosphate. The higher dietary phosphorus load was associated with a significantly greater serum phosphate level after 2 h and a significantly lower FMD.

In line with Shuto et al’s results, several clinical trials have reported beneficial effects of lowering phosphate levels on ED. Caglar et al studied 50 nondiabetic, hyperphosphatemic patients at CKD stage 4 and observed that an 8-week course of treatment with sevelamer was associated with less inflammation, higher fetuin-A levels and better endothelial function, compared with calcium acetate.\textsuperscript{25} Yilmaz et al for their part recently reported, in a similar cohort, a modulation of FGF23 levels by phosphate binders, independently associated with improvement of endothelial function.\textsuperscript{26}

In Vitro Studies

Phosphate-induced VC has been extensively studied in recent years, whereas the exploration of phosphate’s involvement in ED is only just emerging. The 2 phenomena share some common underlying mechanisms. After entry via the ubiquitous sodium-phosphate cotransporters Pit-1 and PIT-2, phosphate induces the apoptosis of both vascular smooth muscle cells (VSMCs) and endothelial cells (ECs) resulting in (1) the release of matrix vesicles (MVs) able to calcify blood vessels and (2) endothelial damage. Moreover, by increasing reactive oxygen species (ROS) production, phosphate decreases the bio-availability of nitric oxide (NO), impairs endothelium-dependent relaxation and triggers the osteochondrogenic switch in VSMCs. A number of specific VC- or ED-promoting actions of phosphate have also been reported and are discussed later (Figure 2).

Osteochondrogenic Switch of VSMCs VSMCs cultured with high phosphate levels lose the expression of smooth-muscle specific genes (eg, α-actin, smooth muscle myosin heavy chain and SM22α)\textsuperscript{28} and acquire an osteochondrogenic phenotype. The latter is characterized by osteogenic markers (such as alkaline phosphatase) and upregulation of the Cbfα1/Runx2 transcription factor leading to the synthesis of osteocalcin and osteopontin.\textsuperscript{29,30}

Emerging Role of microRNA (miRNA) in VC Recent research has evidenced the involvement of miRNA in phosphate-induced phenotypic switching. Our lab demonstrated that phosphate induces VC through a mechanism involving the downregulation of miR-145/143, known to be involved in the determination of the contractile phenotype of VSMCs, and the upregulation of miR-223.\textsuperscript{31} Various studies have evidenced the downregulation of miR-125b, miR-221, miR-222, miR-
Vascular Toxicity of Phosphate in CKD

**Release of MVs**  The calcification process induced by phosphate is initiated by the release of calcium/phosphate-rich MVs from living VSMCs. These vesicles contain annexin-II and -VI (membrane-associated proteins known to mediate Ca\(^{2+}\) influx) and are able to calcify extensively.

**Induction of Apoptosis**  Phosphate induces the apoptosis of VSMCs in a time-dependent manner. In turn, apoptosis triggers the release of apoptotic bodies containing preformed calcium/phosphate products and with strong calcification ability.

**Endothelial integrity is essential for normal endothelial function.** Using an ex vivo murine thoracic aorta model, we recently demonstrated that 8 days of exposure to high phosphate levels results in EC loss.\(^{42}\) Di Marco et al reported that high phosphate levels increase ROS production in ECs, causing disruption of the mitochondrial membrane potential and then apoptosis via caspase activation.\(^{43}\)

**Phosphate’s pro-apoptotic effect on ECs has been demonstrated in other studies.**\(^{44}\)

**Increased ROS Production**  The exposure of ECs and VSMCs to high phosphate levels induces the intracellular production of ROS, mainly H\(_2\)O\(_2\), via NADPH oxidase activation.\(^{25,42,44,45}\) H\(_2\)O\(_2\) has been shown to induce the osteochondrogenic switch of VSMCs through Runx2 activation.\(^{46}\)

**Figure 2.** Schematic representation of the mechanisms of phosphate-induced vascular calcification (VC) and endothelial dysfunction (ED). eNOS, endothelial nitric oxide synthase; ICAM, intercellular adhesion molecule; ROS, reactive oxygen species; VCAM, vascular cell adhesion molecule.

---

24-2, miR-27a and miR-31 during in vitro VC under high phosphate conditions. Downregulation of miR-24-2 and 27a, known to be involved in bone formation via inhibition of Runx-2, might lead to a VSMC switch.\(^{32}\) It has been suggested that miR-221 and -222 act synergistically to initiate VC but are then downregulated.\(^{33}\) miR-31 has been shown to be involved in the osteogenic differentiation of mesenchymal cells.\(^{34}\) Lastly, miR-125b downregulation induces upregulation of the transcription factor Ets, a potent repressor of VSMC marker genes.\(^{35}\)

Some authors have stated that phosphate-induced VC may involve the elevation of intracellular Ca\(^{2+}\) concentrations as a result of the induction of miR-135a, miR-762, miR-714, and miR-712, implicated in the repression of transporters involved in Ca\(^{2+}\) efflux.\(^{36}\)

**Elastin Degradation**  Phosphate triggers and accelerates the mineralization induced by elastin-derived peptides.\(^{37,38}\) Whether phosphate also degrades elastin, thus favoring VC, remains to be confirmed.

**Inhibition of Monocyte/Macrophage Osteoclast Differentiation**  We recently demonstrated that phosphate can inhibit osteoclast differentiation into monocytes/macrophages in vitro; this finding strongly suggests that VC is the result of a vascular remodeling process similar to that observed in bone remodeling.\(^{39}\) It remains to be seen whether this mechanism occurs in vivo.
considered as endothelium-derived contracting factors able to induce contraction in dysfunctional endothelium. We recently demonstrated that high phosphate levels have a direct, ROS-mediated vasoconstrictor effect.42

**Decreased NO Production** All the existing studies are consistent on a decrease in NO production after acute exposure to high phosphate levels.43,44 A study using bovine aortic ECs showed that high levels of phosphate decrease the intracellular Ca2+ concentration that could inactivate endothelial NO synthase (eNOS).45 Moreover, high phosphate levels also lead to eNOS phosphorylation (on Thr495) and inactivation through phosphokinase C activation.46,47 We recently demonstrated for the first time that phosphate induces eNOS uncoupling (via the oxidation of tetrabiopterin) in a murine brain EC line.48

**Induction of Microparticle Shedding and Inhibition of Angiogenesis** Endothelial microparticles (EMPs) are vesicles of 0.1–1 µm in size, produced by plasma membrane shedding after cell activation or apoptosis and characterized by the externalization of phosphatidylserine and the presence of EC-specific surface antigens. Some recent findings suggest that EMPs are not only markers of endothelial damage but may also be involved in ED, probably because of their protein content.49

In an elegant study, Di Marco et al50 recently demonstrated that high phosphate levels induces EMP shedding. After observing the large number of annexin-II positive EMPs, the researchers speculated that the induced EMP shedding decreases intracellular levels of annexin-II and thus results in impaired ECs with thrombotic, inflammatory and anti-angiogenic properties.

**Animal Studies**

The in vitro effects of high phosphate levels on VC and ED have been confirmed in vivo in animal models of CKD fed a high-phosphate diet.50–52

In an indirect confirmation of the role of hyperphosphatemia, our team found that the administration of sevelamer or lanthanum to uremic, apolipoprotein-E-deficient mice prevented uremia-induced hyperphosphatemia and slowed both VC and atherosclerosis.53,54 We also reported that calcium carbonate had beneficial effects on VC (despite an increase in calcemia), supporting the predominant role of phosphate in the promotion of VC in CKD.55

We recently characterized the in vivo role of phosphate in the onset and progression of ED, independently of VC.52 We demonstrated that in sham-operated mice, a high-phosphate diet decreased acetylcholine-induced relaxation and increased phenylephrine-induced contraction. These effects of phosphate have been linked to both the loss of ECs and the induction of expression of adhesion molecules, suggesting that phosphate could induce inflammation in vivo. In that study, sevelamer was able to prevent the EC loss in vitro and attenuate ED and the phosphate-associated induction of adhesion molecules in CKD mice. We subsequently used the same animal model to test the effect of sevelamer administration on CKD-related CV abnormalities.56 In line with the observed decrease in both hyperphosphatemia and FGF23 levels, sevelamer treatment reduced ED, aortic stiffness and left ventricular diastolic dysfunction and thus prevented the progression of left ventricular hypertrophy. We reported that sevelamer treatment is also associated with a decreased expression of proteins related to myocardial hypertrophy compared with CKD placebo mice. Interestingly, there was no clear correlation between FGF23 levels and cardiac abnormalities, suggesting that the benefits of sevelamer administration were mainly related to its effects on phosphatemia rather than on FGF23.

**Indirect Effects of Phosphate on CV Calcification and ED**

As mentioned before, phosphate levels are maintained within the normal range in early-stage CKD by a compensatory increase in FGF23 and PTH levels. Notwithstanding the proven association of these phosphate-regulating hormones with CV outcomes, most of the epidemiological studies linking phosphatemia with CV morbidity/mortality have not measured serum levels. Moreover, daily urinary phosphate excretion (a better marker of phosphate load than the serum phosphate level) has rarely been evaluated in these epidemiological studies.

Lastly, the phosphate binders that reportedly reduce VC and ED in animal and clinical studies are also known to modulate FGF23 levels; this makes it more difficult to evaluate the role of phosphate on CVD in vivo.

**PTH**

PTH was first described as a calcium-regulating hormone with direct actions on bone and kidney and indirect effects on the gastrointestinal tract. The elevated levels of PTH seen in CKD are related to phosphate retention and the resulting hypocalcemia. Characterization of the CV effects of PTH has been accelerated by the recent discovery of the PTH receptor in VSMCs and ECs (as well as in cardiomyocytes).57

**Epidemiological and Interventional Studies**

PTH levels are associated with CV mortality even in the general population with a “normal” PTH range. Indeed, in the Uppsala Longitudinal Study of Adult Men, a community-based cohort of elderly men followed up for a median of 9.7 years, plasma PTH levels at the upper limit of the normal range were strongly and independently associated with a greater risk of CV mortality.58

In contrast, increased CV mortality is also found in patients with confirmed primary hyperparathyroidism (PHPT) and secondary hyperparathyroidism, even after parathyroidectomy. Furthermore, some clinical studies have demonstrated that controlling PTH levels (with cinacalcet) in hemodialysis patients does not reduce their CV risk.59–61

Cinacalcet is an allosteric co-activator of the calcium-sensing receptor (CaSR) and acts by lowering the blood Ca2+ concentration needed to inhibit PTH release. An improvement of ED after parathyroidectomy has been reported by Lunachi et al in 22 patients with confirmed PHPT.62 Choi et al63 recently tested the effect of cinacalcet on endothelial function. Their study results demonstrated that cinacalcet alone (ie, in the absence of vitamin D supplementation) improves ED by decreasing oxidative stress and increasing serum NO production. All these various parameters returned to their pretreatment concentrations after withdrawal of cinacalcet.

**In Vitro Studies**

The precise role of PTH on VC is unclear. It has been reported that high PTH concentrations induce in vitro collagen production by VSMCs; in contrast, PTH inhibits calcification in a dose-dependent manner.64

**Animal Studies**

Conflicting results are also found regarding the effect of PTH on VC in animal models. Although Shao et al demonstrated a beneficial effect of PTH administration on CV calcification in diabetic mice,65 Neves et al reported that PTH replacement therapy in parathyroidectomized CKD rats results in aortic calcification.66 These discrepancies may be related to the type of PTH used and the difference in injec-
Vascular Toxicity of Phosphate in CKD

**FGF-23/Klotho Axis**

Isakov et al demonstrated that FGF23 is the first factor to be elevated in the early stage of CKD, to prevent hyperphosphatemia. Membrane-bound Klotho acts as an obligatory coreceptor for FGF23 in the kidney, whereas soluble Klotho functions as an endocrine substance. The reported early and graded decrease in Klotho expression during CKD results in the loss of the ability of FGF23 to decrease both PTH expression and hyperphosphatemia, despite the elevated serum levels of this factor.

**Epidemiological and Interventional Studies**

Elevated levels of FGF23 and decreased levels of Klotho are associated with CV mortality in CKD patients and/or the general population.

An association between variations in FGF23 levels and VC has also been reported. Whether the accumulation of FGF23 exerts protective effect or, on the contrary, is detrimental remains a matter of debate, suggesting the complexity of FGF23 action. Indeed, a study of 142 patients at different CKD stages found that plasma FGF23 levels were positively and independently associated with coronary artery calcium (even in early-stage disease). In contrast, Tamei et al observed a negative association between FGF23 and the progression of aortic arch calcification and suggested that the excessive accumulation of FGF23 may inhibit the calcification process in hemodialysis patients.

Regarding endothelial function, the PIVUS study involving elderly subjects with normal renal function reported an association between circulating levels of FGF23 (within the normal range) on the one hand and impaired endothelium-dependent relaxation, endothelium-independent relaxation and arterial stiffness on the other. Kitagawa et al demonstrated that low serum levels of soluble Klotho are independently associated with vascular stiffness in CKD patients.

**In Vitro Studies**

To date, a direct effect of FGF23 on VC has not been reported. It is widely admitted that Klotho deficiency is harmful. Klotho is able to act directly on calcification by both suppressing the sodium-dependent uptake of phosphate and moderating the osteochondrogenic switch of VSMCs. Thus, the abnormally low Klotho expression observed in CKD might contribute to arterial calcification in vivo. This hypothesis has been challenged recently by Jimbo et al who demonstrated that FGF23 amplifies the phosphate-induced VC in condition of Klotho overexpression.

Moreover, Klotho maintains endothelial integrity by regulating Ca²⁺ influx in ECs.

Concerning the action of FGF23 on ED, we recently dem-

---

**Figure 3.** Potential role of phosphate in vascular damage: beyond chronic kidney disease (CKD). A systemic phosphate burden can result from a high dietary phosphate load or a low number of functional nephrons (as in CKD). In CKD, elevated production of FGF23 and parathyroid hormone (PTH) (which normally reduces the phosphate burden) leads to hyperphosphatemia and vascular alterations. The endothelial dysfunction caused by a long-term excessive phosphate burden (from a Western diet) may constitute the link between high-normal phosphate levels and cardiovascular mortality in the general population.
Phosphate levels are associated with CV risk in both CKD patients and the general population. We have summarized recent data concerning the direct and indirect effects of hyperphosphatemia on VC and ED. Nevertheless, the mechanisms underlying the association between high-normal phosphate levels and CV risk in the general population have yet to be characterized. Many in vitro and in vivo studies have highlighted an acute effect of hyperphosphatemia on ED. The high phosphate content of the Western diet may cause long-term, excessive phosphate loading (without overt hyperphosphatemia) that leads to ED and then CVD. It is noteworthy that post-prandial blood glucose elevation is a well-established risk factor for CVD. Hence, ED caused by post-prandial hyperphosphatemia could be the link between high-normal phosphate levels and the CV risk in the general population (Figure 3).

Conclusions

Phosphate levels are associated with CV risk in both CKD patients and the general population. We have summarized recent data concerning the direct and indirect effects of hyperphosphatemia on VC and ED. Nevertheless, the mechanisms underlying the association between high-normal phosphate levels and CV risk in the general population have yet to be characterized. Many in vitro and in vivo studies have high-lighted an acute effect of hyperphosphatemia on ED. The high phosphate content of the Western diet may cause long-term, excessive phosphate loading (without overt hyperphosphatemia) that leads to ED and then CVD. It is noteworthy that post-prandial blood glucose elevation is a well-established risk factor for CVD. Hence, ED caused by post-prandial hyperphosphatemia could be the link between high-normal phosphate levels and the CV risk in the general population (Figure 3).
