Optical Frequency Domain Imaging and Intravascular Ultrasound for Adult-Onset Kawasaki Disease in the Sub-Acute Phase

Toshiki Kuno, MD, PhD; Akimichi Shibata, MD; Masaki Kodaira, MD, PhD; Yohei Numasawa, MD, PhD

We previously reported on an 18-year-old patient with adult-onset Kawasaki disease (KD). Given that the coronary computed tomography angiography showed a coronary artery aneurysm (CAA) along the left anterior descending artery (LAD) and the patient complained of chest pain, we performed coronary angiography 5 months after onset. Angiography showed the CAA along the LAD and the irregular vessel wall of the right coronary artery (RCA; Figure A, B). Notably, optical frequency domain imaging (OFDI; FastView, Terumo) and intravascular ultrasound (IVUS; ViewIt, Terumo) showed intimal thickening without calcification in the CAA along the LAD (Figure C, D, Movie S1). In addition, OFDI and IVUS indicated diffuse intimal thickening along with the aneurysmal changes in the RCA (Figure E, F). The fractional reserve flow in the LAD was 0.89. OFDI and IVUS of KD usually show severe calcification in the later phase. In the present case, however, CAA with intimal thickening without calcification was seen because coronary angiography was performed in the subacute phase. This is extremely rare because most patients with KD are children, and we cannot perform intravascular imaging for children in that phase.
