Abstract:

We proposed and investigated novel methods for polarization demultiplexing using artificial neural networks (ANNs). It was shown that a three-layer ANN includes butterfly operations and has a polarization-demultiplexing capability. Our proposed cascaded construction of a butterfly-structure of FIR filters and an ANN connecting x- and y-polarization components exhibited superior performance in terms of the polarization-demultiplexing speed. By using the proposed method, optical nonlinearity can also be compensated for at the same time. We examined and compared the performance of the proposed methods by numerical simulations using 10-Gsymbol/s polarization multiplexed 16QAM optical signals.

1 Introduction

In digital coherent optical communication systems, digital signal processing (DSP) is playing an important role in realizing not only carrier-phase estimation but also polarization demultiplexing and linear compensation of waveform distortion caused by, e.g., chromatic dispersion and polarization-mode dispersion (PMD) [1,2]. Optical nonlinearity compensation in the digital domain is regarded as the next significant step in compensating for nonlinear effects such as self-phase modulation (SPM) and cross-phase modulation (XPM). Some algorithms have been investigated to realize a digital nonlinear equalizer, including digital back propagation (DBP) and the Volterra series transfer function (VSTF) [3,4]. However, one drawback is the enormous amount of calculations required, which causes time delays and increases the power consumption at the receiver. Artificial neural networks (ANNs) have been investigated as another candidate which can realize digital nonlinear equalizers to compensate for optical nonlinear effects [5-8]. One important merit of using an ANN is its ability to decrease the computational complexity of the nonlinear equalizer [9]. In those studies, ANN-based nonlinear equalization has been performed on single-polarization signals or signals after a polarization demultiplexing process. In our study, we
clarified that polarization demultiplexing can be performed using an ANN because an ANN includes butterfly operations [10]. We investigated novel methods using ANNs to perform polarization demultiplexing and nonlinear compensation at the same time. In this paper, we compared the performance of these methods under various conditions of input optical power to the optical fiber. The investigation revealed that our proposed cascaded construction of a butterfly-structure of FIR filters and an ANN connecting x- and y-polarization components had superior performance in terms of the polarization-demultiplexing speed.

2 Polarization demultiplexing and nonlinear compensation

In a digital coherent receiver, polarization demultiplexing is performed by using butterfly-structured FIR filters [1,2]. However, it can be considered that polarization demultiplexing can also be performed using an ANN because an ANN includes butterfly structures. Here, we compare an FIR filter and a two-layer ANN. Figure 1(a) shows an FIR filter. Delayed signals are multiplied by filter coefficients and summed. The same operation is performed in a two-layer ANN with a tapped delay line, as shown in Fig. 1(b). The unit in the output layer performs a weighted sum of the signals from the input-layer units. Figures 1(c) and (d) show butterfly-structured FIR filters and a two-layer ANN with two-channel tapped delay lines, respectively. In Fig 1(c), $h_{xx}$, $h_{xy}$, $h_{yx}$, and $h_{yy}$ show FIR filters in the butterfly structure. Blue lines and red lines denote the connections from the x-port and y-port, respectively. The same operation is performed in the two-layer ANN, as shown in Fig. 1(d). The two units in the output layer of the ANN output demultiplexed x- and y-polarization components of the signal.

Figures 2(a) to (d) show four methods. We compared the polarization demultiplexing and optical nonlinearity compensation performance of these methods. Figure 2(a) shows a simple butterfly structure of FIR filters, which is generally used for polarization demultiplexing (method 1). Figure 2(b) shows a conventional method (method 2), in which an independent ANN compensates for the optical nonlinearity of each polarization component after polarization demultiplexing. However, one drawback of this method is that the independent
ANNs cannot compensate for XPM between the two polarization components because of the lack of information interchange between the demultiplexed polarization components. Figure 2(c) shows our proposed novel method (method 3), in which one ANN compensates for the nonlinear waveform distortion of the two polarization components after the polarization demultiplexing. Figure 2(d) shows another proposed novel method (method 4), in which an ANN works for polarization demultiplexing and optical nonlinearity compensation at the same time.

3 System Setup

Figure 2(e) shows an optical-fiber transmission system used in our simulations. A 10-Gsymbol/s polarization multiplexed 16QAM optical signal was modulated by PRBS $2^{11}-1$ data and transmitted by a 20-km standard single mode fiber (SSMF). The wavelength of the laser diode (LD) was 1552.5 nm. The noise figure of the Er-doped fiber amplifier (EDFA) was 3 dB. A polarization controller (PC) was used to adjust the state of polarization (SOP) of the transmitted optical signal. The optical signal was received by optical homodyne detection using an optical 90°-hybrid and balanced photodetectors (BPDs). The power of the local oscillator was 3 dBm. Here, we assumed that the LO was ideally synchronized to the optical signal. For polarization demultiplexing and nonlinear compensation, DSP based on the four methods in Fig. 2(a) to (d) was performed. The number of hidden layer

of each ANN in the methods was set to 15. The number of taps was set to 11. The ANNs and the FIR filters were trained by a least mean squares (LMS) algorithm using PRBS 2\textsuperscript{11}-1 data. We confirmed that over-training did not occur, by testing the results using some other PRBS data such as 2\textsuperscript{9}-1 and 2\textsuperscript{15}-1, which is needed to eliminate overestimation [11].

4 Results and discussion

First, we adjusted the input power to the SSMF to 0 dBm for the x-polarization and 12 dBm for the y-polarization. In this case, SPM is observed only on the y-polarization component. On the other hand, we can observe XPM only on the x-polarization. Figure 3(a) shows the constellations of the x- and y-polarizations of the received signal without any DSP. The waveform was completely distorted by polarization crosstalk, optical nonlinearity and dispersion. Figure 3(b) shows the constellations of the x- and y-polarization components after the processing using method 1. In this case, polarization demultiplexing and dispersion compensation were performed by the FIR filters. However, XPM on the x-polarization and SPM on the y-polarization could not be compensated for. Figure 3(c) shows the constellations of the x- and y-polarizations after the processing using method 2. In this case, SPM on the y-polarization component was compensated for by the ANN for the y-polarization. However, XPM on the x-polarization could not be compensated for because the ANN for the x-polarization did not have any information about the y-polarization signal. Figure 3(d) shows the constellations of the x- and y-polarizations after the processing using method 3. In this case, both XPM on the x-polarization and SPM on the y-polarization could be compensated for. Figure 3(e) shows the constellations of the x- and y-polarizations after the processing using method 4. In this case, the polarization demultiplexing and the compensation of XPM and SPM were successfully performed as well. There was no significant difference between the compensation performance of method 3 and that of method 4. Figures 3(f) and (g) show the mean-square errors of the x- and y-polarization signals versus the number of iterations of the learning steps, respectively. We performed the learning processes 10 times for each method, while changing the SOP of the incoming signals and the random initial values of the parameters of the ANNs and the FIR filters. By employing method 3 or 4, the error was successfully minimized on both the x- and y-polarizations. However, it should be noted that the convergence speed of the learning of method 3 was faster than that of method 4. Next, we adjusted the input power to the SSMF to 12 dBm for both the x- and y-polarizations. In this case, the optical signals on both the x- and y-polarizations are distorted by SPM and XPM. Figure 3(h) shows the constellations before DSP. Figure 3(i) shows the constellations after the processing of method 1. The nonlinear distortions caused by SPM and XPM were not compensated for. Figure 3(j) shows the constellations after the processing of method 2. In this case, only the effect of SPM was compensated for by the ANNs. However, XPM was not compensated for. Figures 3(k) and (l) show the constellations after the processing of methods 3 and 4, respectively. In these cases, the polarization demultiplexing and the nonlinear compensation of SPM and XPM
were successfully performed. Figure 3(m) shows the mean-square errors of the signals on the x-polarization versus the number of iterations of the learning steps. Also in this case, the convergence speed of the learning of method 3 was faster than that of method 4. From the results above, we conclude that the performance of method 3 is superior to method 4 from the viewpoint of polarization demultiplexing speed.

5 Conclusion

We investigated methods for polarization demultiplexing and nonlinear compensation using ANNs. We showed that an ANN could perform polarization demultiplexing and nonlinear compensation at the same time. Our proposed cascaded construction of a butterfly-structure of FIR filters and an ANN connecting x- and y-polarizations showed superior performance in terms of polarization demultiplexing speed and optical nonlinearity compensation.
