Received September 3, 2013; accepted November 7, 2013

Topical administration of clotrimazole represents the common use therapy in the antimycotic genitourinary tract treatment. Due to the fast self-cleaning action of the vagina, commercially available vaginal dosage forms with clotrimazole cannot assure prolonged contact time with mucosa, therefore the main objective of this study was to develop a dosage form for vaginal administration of clotrimazole using chitosan—a biodegradable and biocompatible derivative of chitin. Tablets mucoadhesive properties were examined using texture analyser under the presence of porcine vaginal mucosa and two different models of adhesive layers—mucin gel and gelatine discs. In addition, friability, hardness, swelling behaviour, residence time, surface morphology of the performed tablets, the in vitro release profile of clotrimazole and clotrimazole release kinetics were determined. The release of clotrimazole from formulations with 25 or 40% of chitosan (F2 and F3) followed non Fickian diffusion through chitosan-gel layer and was retarded up to 6 h. Additionally, tablets F2 showed the best results in terms of mucoadhesive properties and appeared to be a good alternative to commercially available antimycotic vaginal dosage forms.

Key words chitosan; mucoadhesive tablet; vaginal delivery; clotrimazole; texture analyser; mucoadhesion

Mycotic vaginosis (MV) is commonly occurring vaginal infection often associated with a feeling of discomfort and inconvenience. MV affects up to 75% of women at least once during their lives with a high risk of disease recurrence.1,2) The conventional treatment of MV is based on combining drugs administered by both oral and vaginal routes. Vaginal drug delivery offers a great number of advantages including the hepatic first pass-effect bypass, low systemic drug exposure, ease of administration and improved bioavailability compared with the oral route.3) For many years, imidazole derivatives like clotrimazole (CLO) (Fig. 1) have been used as the drugs of choice for the mycotic infections of the genitourinary tract treatment due to their good therapeutic responses. CLO is available in several conventional vaginal dosage forms, such as creams, ovules and tablets,4) which do not offer prolonged delivery of the drug. Hence, it seems to be essential to develop novel formulations with increased drug residence time in the site of infection. In the recent years, the development of vaginal mucoadhesive preparations as a type of sustained release form for topical diseases treatment has gained great attention.5–7)

Chitosan is one of the natural mucoadhesive polymers. It is a copolymer consisting of glucosamine and N-acetylglucosamine units, which is obtained by deacetylation of chitin derived mainly from exoskeleton of crustaceans. The importance of chitosan especially in biomedicine and pharmaceutical industry has arisen from its excellent properties such as biocompatibility, biodegradability and non-toxicity. It is currently known that chitosan is biodegraded by a number of enzymes, such as lysozyme, di-N-acetylglucosaminidase, N-acetyl-beta-D-glucosaminidase and chitotriosidase, which are present in human mucosa and other physiological fluids. Biodegradation of chitosan leads to the release of non-toxic oligosaccharides, which can be incorporated to glycosaminoglycans and glycoproteins or be excreted.8–10) Among polycations, it has received considerable attention for its safety—recent studies have shown that chitosan and its derivatives had no cytotoxic effect on vaginal epithelial cells.11,12) Chitosan is also reported to show penetration enhancement properties by improving the active agent transport through epithelium layer containing tight junctions.12) In addition, it possesses antibacterial and antifungal activity13) and due to its good mucoadhesive properties resulted from the cationic behaviour and the presence of free hydroxyl and amine groups enabling polymer to interact with mucin by hydrogen and electrostatic bonding—chitosan is regarded as a suitable excipient to prepare buccal and vaginal dosage forms.14,15)

The aim of this work was to design mucoadhesive vaginal tablets by using chitosan as a matrix in order to improve drug residence time compared to commercially available dosage forms with CLO. The prepared tablets were analysed for weight uniformity, diameter, thickness, friability, hardness, moisture content, surface morphology, CLO content uniformity and the in vitro release. To evaluate the mucoadhesive properties of the designed tablets, swelling index, the in vitro 

Fig. 1. Chemical Structure of CLO
residence time, maximum detachment force and work of adhesion in the presence of porcine vaginal mucosa were examined. Regarding the fact that mucoadhesive properties can be determined using different experimental conditions, the objective of this study was also to investigate the usefulness of two different mucosa surrogates as simple adhesive models imitating vaginal mucosa–gelatin rings and mucin gel.

Experimental

Materials Chitosan (medium molecular weight (MMW), with 75–85% of deacetylation degree, viscosity of 1% solution in 1% acetic acid: 200 cP) (Sigma-Aldrich, Steinheim, Germany), Prosolv SMCC-50 (silicified microcrystalline cellulose) and Pruv (sodium stearyl fumarate) (JRS Pharma, Rosenberg, Germany), Tablettose 80 (spray-dried lactose) (Cardinal Pharma Ltd., Lodz, Poland), potato starch (Galfarm, Krakow, Poland) were used for tablets preparation. Clotrimazole was a gift from Ziaja Ltd. (Gdansk, Poland). Commercially available vaginal tablets with CLO (CLOTIRMAZOLUM GSK 100 mg; GlaxoSmithKline Pharmaceuticals SA, batch no: RB 2361, expiry date: 02.2014) were purchased locally and used as a control. Porcine vaginal mucosa from Large White Pigs weighting ≈200 kg was obtained from veterinary service of Bost slaughterhouse (Turosn Koscielna, Poland). Freshly excised tissue was washed and frozen at −20°C immediately after an animal was sacrificed. Samples were defrosted just before the experiment at ambient temperature and cut into 2 cm long and 2 mm thick pieces. Eighty percent acetic acid, sodium acetate, potassium dihydrogen phosphate, sodium hydroxide and di-sodium hydrogen phosphate were obtained from Chempur (Piekary Slaskie, Poland). Freshly excised tissue was washed and frozen at −20°C immediately after an animal was sacrificed. Samples were defrosted just before the experiment at ambient temperature and cut into 2 cm long and 2 mm thick pieces. Eighty percent acetic acid, sodium acetate, potassium dihydrogen phosphate, sodium hydroxide and di-sodium hydrogen phosphate were obtained from Chempur (Piekary Slaskie, Poland). Methanol was HPLC grade and it was purchased from Merck (Darmstadt, Germany). Water for HPLC was distilled and passed through a reverse osmosis system Milli-Q Reagent Water System (Billerica, U.S.A.).

Preparation of Vaginal Tablets Tablets containing 100 mg of CLO and weighting approximately 500 mg were prepared by direct compression method using the single punch eccentric tablet press EP-1 (Erweka, Heusenstamm, Germany) fitted with round, flat-faced 12 mm punches and running at a speed of 20 rpm. The blended powder was mixed in a mortar fitted with round, flat-faced 12 mm punches and running at a speed of 20 rpm. a) Percentage of chitosan.
stage. Images were collected after 3 min pumping at 15 kV with back-scattered electrons (BSE) detector and in the low vacuum mode.

**Differential Scanning Calorimetry (DSC)** DSC thermograms were performed using a differential scanning calorimeter Q2000 (TA Instruments, New Castle, U.S.A.). Samples (4–6 mg) were placed into the covered aluminum pans and heated from 30 to 280°C at a heating rate of 30°C per minute. The scans were taken under nitrogen atmosphere. An empty covered aluminum pan was used as the reference.

**Swelling Index (SI) Studies** Each tablet was weighted and placed separately in a 25 mL beaker containing 5 mL 0.08 m acetic buffer (pH 4.5) at 37±0.5°C. At the predetermined time intervals (0.25, 0.5, 0.75, 1, 2, 3, 4 h) tablets were removed, wiped off with filter paper and reweighted. The swelling index was calculated by using the following formula:

\[ SI = \frac{W_2 - W_1}{W_1} \]  

(1)

where SI is the swelling index, \( W_1 \) is the initial weight of the tablet, \( W_2 \) is the weight of the tablet after the particular swelling time interval. Each experiment was performed in triplicate.

**In Vitro Release Study** *In vitro* release study was carried out using USP dissolution apparatus II (Erweka Paddle Dissolution tester Type DT 600HH, Heusenstamm, Germany). The dissolution medium was 900 mL of 0.08 m acetic buffer (pH 4.5) with addition of 1% surfactant maintained at 37±0.5°C and stirred at 75 rpm. Samples of 2 mL were withdrawn at the predetermined time intervals (0.25, 0.5, 0.75, 1, 2, 3, 4, 5, 6, 7 h), filtered through 0.45 μm cellulose acetate paper filters, diluted with methanol and analysed using the HPLC method.\(^{21-23}\) Withdrawn samples were replaced with equal volumes of the fresh medium. Sink conditions were maintained throughout the experiment. Studies were conducted for six tablets from each formulation.

**CLO Release Kinetics** In order to investigate the kinetics governing CLO release, the obtained drug release profiles were fitted to presented below mathematical models.\(^{24,25}\)

**Zero order equation:**

\[ f_t = k_0 \times t \]  

(2)

**First-order equation:**

\[ f_t = f_{\text{max}} \times (1 - \exp^{-kt}) \]  

(3)

**Higuchi equation:**

\[ f_t = \sqrt{kt} \]  

(4)

**Korsmeyer–Peppas equation:**

\[ f_t = k_2 \times t^n \]  

(5)

where \( f_t \) is the fraction of the drug released in time \( t \), \( k_0 \) is the zero order kinetic constant, \( f_{\text{max}} \) is the maximum fraction of the drug released during process, \( k_1 \) is the first order kinetic constant, \( k_2 \) is constant incorporating structural and geometric dosage form, \( K \) is constant reflecting the design variables of the system, \( n \) is the release exponent indicating the drug release mechanism.

**Determination of the Residence Time** The *in vitro* residence time of designed tablets was determined using a self-constructed apparatus (by modifying USP Disintegration tester Electro lab ED-2L, Mumbai, India), according to Nakamura et al.\(^{26}\) Segments of porcine vaginal mucosa (2 cm long) were glued on the internal side of a beaker above the level of 500 mL 0.08 m acetic buffer (pH 4.5) at 37±0.5°C. After moisturizing the chitosan tablet with 100 μL of acetic buffer (pH 4.5), a hydrated surface was put in contact with the mucosal membrane by applying a fingertip force for 30 s. A plexiglass cylinder (6 cm diameter, weight 280 g), which was vertically fixed to the apparatus was enabled to move up and down to assure the immersion of the tablet completely in the buffer solution. The time required for entire detachment of the tablet from the vaginal mucosa was noted.

**Determination of the *In Vitro* Mucoadhesive Properties (Maximum Detachment Force and Work of Adhesion) Using Texture Analyser** TA.XT.Plus Texture Analyser (Stable Microsystems, Godalming, U.K.) equipped with 5 kg load cell, cylinder probe and the measuring system A/MUC was used for mucoadhesion test. The *in vitro* mucoadhesive properties of chitosan tablets were assessed on porcine vaginal mucosa, gelatine discs and mucin gel which were placed on the platform below the texture analyser probe. Gelatine discs (20 mm in diameter, 2–3 mm in height) were prepared by pouring 30% (w/w) aqueous solution of gelatine over a Petri plate and left for jellification, while 10% mucin gel was absorbed on a cellulose fiber (20 mm in diameter). The tests were conducted at 37±0.5°C. The surface of mucoadhesive material (except mucin layer) was moisturized with 100 μL of 0.08 m acetic buffer (pH 4.5). An acquisition rate of 200 points/s and a trigger force of 0.003 N were selected to all measurements. Each tablet was adhered to an upper probe with α-cyanoacrylate glue and lowered onto the surface of the adhesive material with a constant speed of 0.5 mm/s. After keeping a contact time for 100 s under an initial contact force (1 N), which the parameters were determined during preliminary experiments (data not shown), the two surfaces were separated at a constant rate of 0.1 mm/s. The maximum detachment force \( F_{\text{max}} \) as a function of displacement was recorded directly from Texture Exponent 32 software and the work of mucoadhesion \( W_{\text{ad}} \) expressed in μL, was calculated from the area under the force versus distance curve. Commercially available tablets with CLO were used as a control. Each experiment was carried out six times.

**Statistical Analysis** Quantitative variables were expressed as the mean±standard deviation and the median. A statistical analysis was performed using nonparametric techniques: the Kruskal–Wallis and Mann–Whitney U-test with the Statistica 10.0 software. Differences between groups were considered to be significant at \( p<0.05 \).

**Results and Discussion**

**Tablet’s Physical and Chemical Properties** Poor retention at the administration site of the conventional vaginal formulations with CLO and leakage caused by vertical posture results in impaired therapeutic efficiency of the drug and requires multiple daily applications. In order to overcome these limitations, it is essential to develop novel dosage forms, which ensure prolonged release of the drug in the vaginal
cavity. In the present study to obtain mucoadhesive vaginal tablets with CLO, chitosan MMW with a degree of deacetylation 75–85% was employed because of its good tableting properties and suitability for obtaining mechanically stable tablets. During preliminary tableting studies with different powder blends (data not shown), a suitable type and amount of excipients were selected (Table 1). Low values of deviation from mean mass, diameter, height and hardness of the formulations F1–F3 confirmed a high uniformity of the produced tablets (Table 2). Friability and moisture’s content of these formulations were less than 0.525% and 1.17%, respectively (Table 2). Friability and moisture’s content of these formulations (less than 0.525% and 1.17%, respectively) was in the acceptable range. Tablets F4 was mechanically unstable, which demonstrated that 50% of chitosan employed in the tablet mass was not able to confer compactness of the formulation. However, there were reports confirmed attempts of producing tablets with even more than 80% of chitosan in a tablet, but due to different composition and destination of the designed formulations, these data are not comparable. According to obtained data of physical properties (Table 2), formulations F1–F3 were selected for further investigations.

**SEM and DSC Studies** To assess the surface morphology of tablets F1–F3, SEM studies were carried out. SEM photomicrographs showed heterogeneous mixture of excipients with CLO crystals clearly seen inside pores, fissures and cracks. The most intact surface with a few void spaces was observed in formulation F1, whereas formulation F3 (with the highest amount of chitosan) showed the most porous structure (Fig. 2). In order to exclude possible interactions between CLO, chitosan and other excipients used, DSC analysis was conducted. Physical and mechanical properties of chitosan, which is an amorphous polymer are connected with its stretching chain and state–glassy or rubbery. Therefore, it was interesting to investigate whether the presence of crystalline CLO influenced amorphous chitosan. Pure CLO exhibited a sharp endothermic peak of 146.72°C (∆H = 667.6 J/g), corresponding to its melting point. No significant changes in CLO thermal profiles among analysed formulations were noticed, but broad endothermic peaks between 98 and 104°C (∆H in a range of −96.3 to −241.1 J/g) were observed on chitosan DSC thermograms (Fig. 3). An observed shift to lower temperature and decrease in chitosan endothermic peak size in F1–F3 thermal profiles might be caused by the loss of physically adsorbed water or point on alteration the polymer state from glassy to rubbery.

**SI Studies** Mucoadhesion mechanism of swellable polymers is directly connected with water uptake into tablet matrix and gel layer formation, therefore formulations F1–F3 were submitted to swelling study in order to investigate tablet hydration capability. Adhesion occurs shortly after beginning of swelling and increases with the degree of hydration of polymer. However, excessive level of swelling reduces the mucoadhesive properties because the polymer groups necessary to link mucin chains are bound by water molecules. The swelling profiles, represented as the swelling index (SI; Eq. 1) versus time are reported in Fig. 4A. All investigated formulations’ curves showed an initial rapid increase within 15 min due to the entry of water via metastable pores known as hysteresis of swelling mechanism and reached the highest value after only 30 min of the study in the order F2 > F1 > F3. Formulation F2 (with 25% of chitosan) showed the highest swelling index (5.45), while tablets F3 with 40% of chitosan attained significantly lower value of SI (3.81). Formulation F1 registered 50% weight loss after 2 h as a result of tablet erosion. On the contrary, tablets F2 and F3 were compact during the study and only a slight drop in SI at the end of the test occurred. The obtained results indicate that as the concentration of chitosan increased from 10 to 25%, the swelling index increased as well, but further rise in polymer concentration (up to 40%) caused a significant decrease in water uptake. As chitosan becomes hydrated and forms a swollen gel, dissolution and surface erosion occurs simultaneously and this phenomena are slower and less intensive when higher concentrations are used. For this reason, tablets F2 and F3 showed higher integrity than F1.

**Drug Release Studies** The in vitro release profiles of CLO from formulations F1–F3 and commercially available non-modified release vaginal tablets with CLO (used as a control) are shown in Fig. 4B. Formulation F1 showed the highest initial release rate of CLO, comparable to that obtained from control (almost 100% of CLO released during the first hour of the study). The release of CLO from formulations F2 and F3 was retarded up to 6 h and 80% of CLO was released after 4 and 5 h, respectively (Fig. 4B). Hydration and gel formation ability of chitosan in acidic pH, leading to early clogging of pores in the tablet matrix hinder the entrance of water, and as a result, much slower disintegration and drug dissolution rate is observed.

In order to investigate what mechanism is responsible for prolonged CLO release, dissolution data obtained for formulations F2 and F3 were fitted to zero order, first order equations, Higuchi model (applied for matrix systems) and Korsmeyer–Peppas model (employed for swellable matrices) (Eq. 2–5 in

*Not tested.*
Formulation F1 was not kinetically evaluated because it was out of targeted profile limits. The calculated parameters from equations are shown in Table 3. The approximation accuracy of an individual model was defined on the basis of the regression correlation coefficient values with the acceptance of $R^2 \geq 0.97$. The release mechanism can be controlled by polymer chain relaxation time and water penetration rate, responsible for hydration and drug diffusion. In case of cylinder shape tablets, the value of diffusional exponent $n = 0.89$ indicates on a combination of diffusion and swelling control on release mechanism. It was noticed that mechanism of CLO release from F2 and F3 did not follow case II transport but was diffusion controlled first order kinetics as the plots showed higher regression correlation coefficient (Table 3). However, based on Korsmeyer–Peppas equation, the obtained values of diffusion exponent for the formulation F2 and F3 indicated on anomalous diffusion characteristic for swelling-controlled systems. Lower value of $n$ in the case of formulation F2 (with the highest hydration level) suggests that diffusion control mechanism has the edge over the polymeric chain relaxation and may be explained by higher CLO–chitosan ratio in tablets F2. Higher amounts of CLO compared to the polymer in F2 may interfered with the chitosan macromolecular chain relaxation process, thus leading to a suppression of the relaxational mechanism. With the rise in chitosan content (F3), polymeric chain relaxation process enhanced and the $n$ value increased.

**Mucoadhesion** In order to investigate tablets behaviour in contact with mucosal surface and to determine residence time at the site of administration, mucoadhesive studies were performed. The *in vitro* residence time of designed tablets was determined using a self-constructed apparatus, according to Nakamura et al. A plexiglass cylinder, which was vertically fixed to the apparatus was enabled to move up and down to assure the immersion of the tablet completely in the 0.08 M acetic buffer (pH 4.5) solution and the time required for entire detachment of the tablet from the porcine vaginal mucosa was noted. Porcine vaginal mucosa was used for simulation of vaginal mucoadhesion due to similarity of porcine and human vaginas in terms of anatomical structure, pH, vaginal secretion and cervical mucus production. Comparative studies of human and porcine vaginal mucosa revealed similarities in the morphology—both possess a nonkeratinized, stratified and squamous surface epithelium differentiated only in thickness (human: about 150–200 µm, porcine: 116 µm) and demonstrated the striking similarities in barrier composition and permeability. Moreover, experiments with porcine mucosa application allow to replace highly expensive and requiring Bioethics Committee approval *in vivo* studies. It was observed that all examined tablets adhered immediately to the mucosal surface and the contact time of formulations F2 and F3 with vaginal tissue was significantly higher than control tablets (Fig. 5A) and was correlated with chitosan concentration (tablets F2 and F3 had significantly longer residence time than F1). Mechanism of chitosan mucoadhesion involves both physical and secondary chemical interactions. Physical bonds imply the entanglement followed by interpenetration of mucin chains in the swollen chitosan matrix. Second chemical interactions include hydrogen bonding and—recognised as the primary mechanism of action—electrostatic interactions between positively charged amino groups in chitosan and the negatively charged mucus gel layer.

The evaluation of mucoadhesive properties of tablets F1–F3 was additionally performed using texture analyser. Replacement of animal mucosa with the appropriate adhesive model can simplify the analytical procedure and improve reproducibility of the experiment, therefore the usefulness of gelatine rings and mucin gel for measurement of mucoadhesiveness of chitosan tablets were also examined. The effect of chitosan concentration on the force of detachment ($F_{\text{max}}$) and work

Fig. 3. DSC Thermograms of Chitosan (CHN), Clotrimazole (CLO), and Tablet Formulations F1–F3

Fig. 4. Swelling Index Study of Formulations F1–F3 and Control (A) and the *in Vitro* CLO Release Profiles from Formulations F1–F3 and Control–Commercially Available Vaginal Tablets with CLO (B)
required to overcome the tablet–adhesive material interaction ($W_{ad}$) is presented in Figs. 5B, C. All examined tablets showed mucoadhesive properties expressed as $F_{max}$ with the range of 0.31 to 1.04 N and $W_{ad}$ between 86.9 and 1021.7 $\mu$J. In general, the strength of mucoadhesive bond increased, by increasing the concentration of chitosan in the formulations. The highest values of $F_{max}$ and $W_{ad}$ evaluated by using three different adhesive models were observed for formulation F3 (values obtained by using porcine vaginal mucosa: $F_{max}$ 0.747 ± 0.188 N; median 0.671, $W_{ad}$ 1021.7 ± 365 $\mu$J; median 961.3). It was also found that both model mucosa surrogates can be successfully used to examine the mucoadhesiveness of chitosan tablets, however gelatine ensured better correlation to porcine mucosa and ensured higher reproducibility of the experiments (Figs. 5B, C). As $F_{max}$ and $W_{ad}$ between F2 and F3 were not found significantly different ($p>0.05$), a plateau in mucoadhesive properties of F2 tablets was noticed, beyond which no obvious rise in tablets mucoadhesive strength could be achieved. The obtained results were confirmed by swelling index studies (Fig. 4A) and showed a direct correlation between swelling behaviour and mucoadhesion. In formulation F3, the amount of free water available to produce swelling of mucin decreased as a result of forming compact gel-layer, thus reducing the strength of physical interactions with mucosa. Simultaneously, approximate values of mucoadhesive parameters between F2 and F3 might be explained by possible saturation of all available ionized functional groups of mucin by the positively charged chitosan, pointing on principal part of secondary chemical interactions in mucoadhesive mechanism of chitosan tablets.

**Conclusion**

The obtained results suggest that chitosan can be successfully used as mucoadhesive excipient for vaginal solid dosage forms with CLO. The release of CLO was depended on chitosan concentration and only tablets prepared with 25% and 40% of chitosan (F2, F3) followed the prolonged CLO release. Tablets F2 appear to be the most suitable candidate for CLO delivery with sustained release and prolonged residence time at the mucosal surface. Two different mucosa surrogates—gelatine discs and mucin gel could be successfully used to examine the mucoadhesiveness of chitosan tablets using texture analyser, however gelatine ensured better correlation to porcine mucosa and higher reproducibility of the experiments.
