**Summary** Diploid *Lathyrus boissieri* showed the 7 bivalents in most of pollen mother cells at prophase and metaphase of meiosis. The disturbances in the meiotic stage appeared to have been caused by reciprocal translocation. Meiotic analyses of 232 pollen mother cells indicates occurrence of heterozygotic reciprocal translocation in 94 cells. When the crossing-over and chiasma formation take place in all 4 pairing segments, a ring of 4 chromosomes results, and when the chiasma was absent in one of the 4 pairing segments, a chain of 4 chromosomes results. Of the 94 transtocated MI cells examined, 24 had ring quaderivalents, 55 had open chain quaderivalents and 15 had alternate (zigzag) ring quaderivalents. From the present investigation it appears *L. boissieri* has not acquired stability as yet and translocation has played an important role in its evolution. In this study chromosome count and meiotic behaviour of *L. boissieri* is presented here for the first time.

**Key words** Fabaceae, *Lathyrus boissieri*, Meiosis, Reciprocal translocation.

*Lathyrus* L., from the viewpoint of taxonomy, is placed in the tribe of *Vicieae* which is in the *Fabaceae* (*Leguminosae*) family. It contains about 150–160 species of annual and perennial, autogamous and allogamous herbaceous creeping plant, which occur throughout the temperate regions of the Northern Hemisphere with 52 species in Europe, 30 species in North America, 78 species in Asia, and 24 species extending into tropical East Africa and 24 species into temperate South America (Kupicha 1983, Goyder 1986, Sahin et al. 1998, 2000, Badr 2006). The main centers of diversity are the Mediterranean region, Asia Minor and North America, as well as temperate South America and East Africa (Kupicha 1977, 1981, Jackson and Yunus 1984, Yamamoto et al. 1984, Simola 1986, Schifino-Wittmann et al. 1994, Klamt and Schifino-Wittmann, 2000). There are many species cultivated for forage and human food: *L. sativus* (grass pea), *L. hirsutus* (rough pea), *L. cicera* (flatpodded vetchling), *L. odoratus* (sweet pea), *L. ochrus* (ochrus), *L. sylvestris* (flat pea). Flora Iranica, possessing more than 22 species of the genus *Lathyrus*, belong to nine sections (Neamati 2000). *Lathyrus boissieri*, from the viewpoint of taxonomy, is placed in the section *Lathyrostylis* (Griseb.) Bassler. This taxon is distributed in Iran, Iraq, Turkey and Syria as natural herbaceous. Cytological investigations have shown that all species were diploid with \(2n=14\) chromosomes, that the basic chromosome number of \(x=7\) is constant throughout the genus and that most of the species are diploid (Fedorov 1969, Ornduff 1968–1969, Moore 1970–1977, Goldblatt 1981–1988, Goldblatt and Johnson 1990–2003, Badr 2006, 2007) and some species are natural autopolyploids (Khawaja et al. 1995, 1997, 1998). Some of the diploids have
been doubled artificially by colchicines treatment (Khawaja et al. 1997). Aneuploids are regularly formed in population of autotetraploids, including *Lathyrus* (Khawaja 1996, Khawaja et al. 1998). In this study chromosome count and meiotic behaviour of *L. boissieri* is presented for the first time.
Materials and methods

Chromosome data has been obtained from 2 collections of *L. boissieri*. The first was a single plant origin of Khorramabad (Boojan), Loristan province. The second plant was collected from Avaj (Zanjan province). Floral buds of appropriate size were fixed in absolute ethanol : chloroform : propionic acid (6 : 3 : 2) for 24 h, transferred to 70% alcohol and stored under refrigeration until analyzed. Anthers were squashed and stained in 2% acetocarmine. Chromosome counts were carried out from microspocytes in various stages of meiosis. Chromosomes were studied under oil immersion on an Olympus microscope at a magnification of 320X. Slides were made permanent by venetian turpentine according to the method of Wilson (1945). All slides are retained in the slide collection of the cytogenetics section of the Institute of Biochemistry and Biophysics (IBB). Figures for pollen sterility are based on a minimum of 750 grains stained with lactophenol-cotton blue. Voucher specimens are deposited in the Central Herbarium of Tehran University (HUT).

Results and discussion

The results obtained from meiotic studies in both 2 collections, showed the 7 bivalents in pollen mother cells at first metaphase (Fig. 1). Another stages of meiosis showed chromosome segregation (7–7) at anaphase I and 7 monads segregation at anaphase II (Fig. 2, 3). 7 dyads in each pole of second metaphase were observed (Fig. 4). In diakinesis substage 1 bivalent of chromosomes were associated with nucleolus (Fig. 5).

From the analysis of the dividing pollen mother cells it appeared that in nearly 59.48% of cell normal bivalent formation had taken place (Table 1). The number of ring bivalents in such pollen mother cells ranged from 5 to 7 and the rest were rod bivalents (Fig. 1). The mean number of chiasmata per cell and bivalents were 13 and 1.85 respectively. In 40.51% of PMCs at first metaphase univalent, trivalent and tetravalents were observed (Table 1). The disturbances in the meiotic stage appeared to have been caused by reciprocal translocation. It was observed that the abnormal PMC generally carried tetravalents. The maximum association was found in the form of open chains consisting of 4 chromosomes. Of the 94 translocated MI cells examined, 24 had ring quaderivalents (Fig. 6), 55 had open chain quaderivalents (Fig. 7) and 15 had alternate (zigzag) ring quaderivalents (Fig. 8) (Table 2). According to Table 2, in most of the cases 4 chromosomes have been found to be associated in open chains (58.51%), of which some of

them may be the outcome of adjacent type of translocation (Fig. 9). These are supposed to be responsible for the formation of nonviable pollen grains containing duplication and deficiencies. Results indicates that 37 of the 55 open quaderivalents formed predominantly alternate orientations at first metaphase (Fig. 10), which is in agreement with the results obtained from the pollen stain ability (Table 3). The site of the chiasma formation and of the break in each chromosome may be responsible for the different frequencies of the alternate configuration of the interchange complex in these species. Occasionally in rare cases rod-shaped quaderivalents were observed (Fig. 11). According to Table 3, pollen fertility recorded in our sample showed a value of 64.26%. Here, the presence of trivalents and univalents in rare cases may be explained on the basis that either translocations occurred in 4 chromosomes out of which, involved, leaving the remaining 1 ‘free’ at the time of pairing (Fig. 12). In many plant species individuals with a reciprocal translocation are usually semi–sterile (50% pollen and ovule abortion) and 50% of the meiocytes display the alternate configuration of the interchange complex at metaphase I. Also, in several plant species, plants with a reciprocal translocation are highly fertile and significantly more than 50% of the meiocytes have the alternate configuration (Sybenga 1992).

It is now evident from the above discussions that there is a definite tendency toward translocation heterozygosity in L. boissieri. Form the present investigation it appears L. boissier has not acquired stability as yet and translocation has played an important role in its evolution.
