(Received August 13, 2004)

Melon (Cucumis melo L.) fruits was respectively treated with solutions of 500 mg L⁻¹ of 4-CPA (4-chlorophenoxyaceticacid) and 20 mg L⁻¹ of CPPU (2-chloro-4-pyridyl-N-phenylurea) and then cell size and sugar accumulation in the fruit were investigated. The mean number of cells larger than 200 μm for each rectangular parallelepiped (7-mm long sample serially collected beginning at one end of the 10-mm wide strip removed from the 10-mm thick disk at the maximum transverse diameter of the fruit to the opposite end. Designated as a sample) of the 4-CPA and the CPPU-treated fruits on the 40th day after anthesis (DAA) was 1.4 times higher than that of the control. The mean number of cells smaller than 200 μm per sample of the CPPU-treated fruits on the 55th DAA was 6.5 times higher than that of the control. Mean sucrose content per sample of the 4-CPA and the CPPU on the 55th DAA was 1.7 times as much as that of the control, and the mean glucose and fructose content of the CPPU-treated fruit on the 55th DAA was the highest, being 1.5 times higher than that of the control. Thus, it might be considered that the earlier increase in the number of larger cells in the 4-CPA- and the CPPU-treated melon fruits is related to a larger content of sucrose, and the increase in the number of small cells during the latter period of the CPPU-treated fruits participates in the largest content of glucose and fructose.

Keywords : cell size, 4-chlorophenoxyaceticacid, 2-chloro-4-pyridyl-N-phenylurea, netted melon, sugar accumulation

INTRODUCTION

Sucrose is the main sugar accumulating in melons (Hayata et al., 2000; Kano, 2000; Li et al., 2000; Motomura et al., 1989; Nagao and Nakazumi, 1995) at harvest time. Melon fruit at harvest time contains a large number of cells about 600 μm in diameter (Kano, 2000). Additionally, sucrose accumulates rapidly in the late growing stages in melon fruit with large cells (Kano, 2004). The primary sugar accumulation in grapes is fructose and glucose (Matsui et al., 1979), and the cell size of grapes is about 300 μm maximum at harvest time (Nagakawa and Nanjou, 1965). Fructose accumulates intensively in Japanese pears (Hirata et al., 1969) containing cells of about 200 μm in size (Toyama and Hayashi, 1957). These results suggest that the kind of sugars accumulated in fruits is closely related with cell size in fruits.

Auxin promotes cell enlargement (Collet et al., 2000; Jones et al., 1998; Masuda, 1990). The promotion of fruit development was recognized in melons (Li et al., 2000) and tomatoes (Hayata et al., 1995) using a treatment of 4-CPA (4-chlorophenoxyaceticacid), one of the synthetic auxins. Furthermore, as the treatment of 500 mg L⁻¹ of 4-CPA to melon fruit increased fruit weight (Hayata et al., 2000).
et al., 2000), in this experiment the solution of 500 mg L$^{-1}$ was employed for 4-CPA. In addition, CPPU (2-chloro-4-pyridyl-N-phenylurea), one of the synthetic cytokinins accelerates fruit growth of grapes by cell division (Nickell, 1986). Since the number of cells in melon fruit increased by the treatment of 20 mg L$^{-1}$ of CPPU (Ikeda et al., 1990), a solution of 20 mg L$^{-1}$ was used for CPPU for this experiment. Moreover, cytokinins have also roles in the promotion of cell enlargement (Denizci, 1966).

It is therefore reasonable to consider that auxin and cytokinin have a great influence on cell size and sugar accumulation in melon fruits. In this paper, the effects of 4-CPA and CPPU on cell size and sugar accumulation in melon fruits were investigated.

**MATERIALS AND METHODS**

Earl's Knight Natsukei No.2 (Cucumis melo L.) melon seeds were planted on the seed bed on April 20th, 2000, and nursery plants were spaced at 40 cm intervals in a plastic film greenhouse on May 10th. The flowers that opened around June 15th were used in this experiment. Fruits on the 20th DAA (day after anthesis) were fully sprayed with a 500 mg L$^{-1}$ (2.68 mM) of 4-CPA solution and with a 20 mg L$^{-1}$ (0.10 mM) of CPPU solution. Five fruits were collected on the 40th and the 55th DAA in each treatment, and fruit weights on the 40th and the 55th DAA were investigated. One fruit whose weight was the closest to the average weight for each treatment was chosen, and these fruits were used for cell and sugar analysis.

The most average fruit undergoing each treatment was cut at the maximum transverse diameter, and two approximately 10-mm thick disks from each average fruit from each treatment were excised, one from the maximum transverse diameter toward the calyx end for cell analysis and one from the maximum transverse diameter toward the peduncle end for sugar analysis (Fig. 1). Using a sharp table knife, one strip, 10 mm wide and 10 mm deep, was removed from the disk with 5 mm straddling the maximum transverse diameter line across each disk. Rectangular parallelepipeds which were 7 mm long, 10 mm wide and 10 mm deep (designated as samples) each were serially collected using the same sharp table knife beginning at one end of the strip, proceeding across to the opposite end of the strip. All of the samples in each treatment, other than two end blocks con-
4-CPA AND CPPU AFFECT CELL AND SUGAR

containing the epidermis, were used. These samples in each treatment were dehydrated using various concentrations of alcohol (70%, 80%, 90% and 100%) and were then imbedded in paraffin. Seven 10 μm-thick sections were prepared from these paraffin blocks, and the clearest section from each sample of each treatment was examined under a microscope. As shown in Fig. 2, the maximum diameter of individual cells on the maximum transverse diameter in each sample of the fruit were measured.

Each sample (7 mm in length, 10 mm in width and 10 mm in depth) other than two end samples containing the epidermis were wrapped with cheesecloth and squeezed by pincers to get juice. The juice was diluted 10 times with distilled water. The solution was centrifuged at 8,000 × g for 15 min, and then filtered through a 0.45-μm filter (Millipore, 0.45 μm PTFE, hydrophilic). Twenty μL of the filtrate was injected into HPLC (Shimadzu Inc., Japan) fitted with a refractive index detector (RID. Shimadzu Inc., Japan), equipped with Shim-pack SCR-101C (Shimadzu Inc., Japan), at 0.8 mL min⁻¹ at 80°C. For assessment of the presence and concentrations of each sugar, solutions of 20 g L⁻¹ of sucrose, glucose and fructose were injected into the HPLC before injection of the filtrates. The mean content of sucrose, glucose and fructose was calculated by dividing total sucrose, glucose and fructose contents by the number of the samples.

RESULTS

The weight in the 4-CPA-treated fruits on the 40th DAA was the largest among the fruit treated, but the weight of fruits on the 55th DAA was not significantly different among the treatments (Fig. 3). Cells of the control 40 DAA were dispersed from 50 μm to 400 μm, centering 200 μm but cells of the 4-CPA and the CPPU 40 DAA were dispersed in a range larger than 200 μm

Fig. 2 An illustration of the measurement of the size and the number of cells of melon fruits 40 days after anthesis. White dots indicate the actual cells measured.

Fig. 3 Comparison of the weight among the fruits of the control (open column), 4-CPA-(dotted column) and CPPU-treated (solid column) samples. 40 and 55-day-old fruit; the fruit 40 and 55 days after anthesis, respectively. Values with different letters are significantly different at P < 0.05 using LSD test. Vertical bars are SD (n = 4).
While cells of the control and the 4-CPA 55 DAA were dispersed widely from 50 µm to 600 µm, cells of the CPPU were scattered particularly in a range smaller than 200 µm. The number of samples containing 20 or more cells which were larger than 200 µm in the 4-CPA and the CPPU 40 DAA were twice as large as that of the control, but the number of samples containing 20 and more cells larger than 200 µm 55 DAA was nearly the same among the treatments (Fig. 5). The number of samples containing 10 and more cells smaller than 200 µm in the CPPU 55 DAA was

5, which was 1.7 times as many as that of the control and the 4-CPA. The mean number of cells larger than 200 μm per sample on the maximum diameter of the 4-CPA and the CPPU 40 DAA was around 22, which was much larger than that of the control (Fig. 6). The number of cells larger than 200 μm per sample 55 DAA was not different among the treatments, however the number of cells smaller than 200 μm per sample of the CPPU was 19, which was 16 and 9 larger than that of the control and the 4-CPA, respectively.

The number of samples in which sucrose content was 40 g L\(^{-1}\) or more in the fruit 40 DAA was the largest in the 4-CPA, but the number of samples in which glucose and fructose content was 20 g L\(^{-1}\) or more was the largest in the control (Fig. 7). The number of samples in which sucrose content was 100 g L\(^{-1}\) or more in the fruit 55 DAA was 0, 5 and 2 in the control, the 4-CPA and the CPPU, respectively. The number of samples in which glucose and fructose content was 20
g L\(^{-1}\) or more in the fruit of the CPPU 55 DAA was 5, which were 3 and 5 larger than those of the control and the 4-CPA (Fig. 7). Mean sucrose content per sample of the 4-CPA and the CPPU 40 DAA was not significantly different from the content of the control, but tended to be higher than that of the control (Fig. 8). Mean sucrose content, 99 g L\(^{-1}\) of the 4-CPA, and 108 g L\(^{-1}\) of the CPPU 55 DAA was about 45 g L\(^{-1}\) higher than that of the control (Fig. 8). The mean content of glucose and fructose per sample 40 DAA was around 19 g L\(^{-1}\) in all the treatments, however the content of glucose and fructose in the CPPU 55 DAA was about 26 g L\(^{-1}\), which was around 10 g L\(^{-1}\) higher than those of the control and the 4-CPA, respectively.

**DISCUSSION**

Fruit weight tended to be large in the 4-CPA-treated fruit. The number of cells larger than 200 \(\mu m\) in the fruits was the largest in those treated with 4-CPA. Auxin accelerates the development of melon fruits (Elassar et al., 1974; Masuda et al., 1990) and cell enlargement (Collet et al., 2000; Jones et al., 1998; Masuda, 1990). From these reports it is reasonable to consider that an increase in fruit weight is caused by cell enlargement by 4-CPA treatment. On the other hand, the weight of the CPPU-treated fruit was almost the same as that of the control. While fruit growth of grapes, kiwi fruits and apples is accelerated by CPPU treatment (Gomi et al., 1997; Nickell, 1986), the growth of melon fruit is not affected by CPPU treatment (Li et al., 2000).

Sucrose content in the 4-CPA and the CPPU 55 DAA was about 1.7 times as much as that of the control. The number of cells larger than 200 \(\mu m\) in the 4-CPA and the CPPU 40 DAA was mostly 2 times as many as that of the control. The small vacuoles of meristematic cells increase in size and gradually coalesce as the cell enlarges and ages (Esau, 1964), and most of the imported sugars accumulate in the vacuole of sink-tissue storage cells (Leigh et al., 1979; Yamaki and Ino, 1992). Sucrose content in the vacuole of strawberry fruit increases from 25 to 35 DAA (Ofosu-Anim and Yamaki, 1994). With these results in mind it is reasonable to consider that the content of sucrose accumulated in cells in melon fruit increases due to the coalescence and enlargement of vacuoles by cell enlargement. As mentioned above, 4-CPA has a role in cell enlargement. On the other hand, the cell size of kiwi fruits treated with CPPU is larger than that of the control (Jao et al., 1991; Gomi et al., 1997). Cytokinin-like substances also promote cell enlargement (Denizzi, 1997).
Therefore, it is supposed that the earlier increase of the number of large cells by early 4-CPA and CPPU treatment results in the promotion of the active import of sucrose from an early stage of fruit development.

Glucose and fructose contents in the CPPU 55 DAA was more than 23 g L⁻¹, compared to around 16 g L⁻¹ for the other treatments. The number of cells smaller than 200 μm in the CPPU 55 DAA was much larger than the number in the other treatments. Glucose and fructose accumulate exclusively in young melon fruits (Kano, 2000) or mechanically growth-restricted melon fruits (Kano, 2004) with a large number of small cells, and in Japanese pears with a large number of small cells undergoing CPPU treatment (Kano, 2003). Therefore, it can be stated that glucose and fructose accumulation is promoted during the latter period of melon fruits by CPPU treatment due to the abrupt increase of the number of small cells.

From these results, the following conclusion can be made on sugar accumulation of 4-CPA- and CPPU-treated melon fruits. Sucrose accumulation is accelerated due to the earlier increase in the number of larger cells in 4-CPA- and CPPU-treated melon fruits. The abrupt increase of the number of small cells during the latter period of the CPPU-treated fruits results in a larger content of glucose and fructose.

I express my gratitude to Dr. Walter A. Newport III, Professor at Ishikawa Agricultural College, for his critical reading of the manuscript, and also to Miss Chikako Miyamura for her technical assistance.
