(Received 20 December 2014; Accepted 26 January 2015; Published 14 February 2015)

The increasing importance of the volume expansion effect on crystalline materials induced by ion-beam irradiation has drawn much attention because of its applications. For example, the expansion effect is used as a good probe to investigate any crystalline-amorphous (c-a) phase change and/or damage. Because the expansion rate and its depth profile can be controlled by means of the irradiation parameters, such as fluence and energy, the deformation of structures on the micro-/nano-meter scale is expected. The fluence needed to achieve deformation is relatively low, and it is expected that irradiation-induced damage is reduced compared with that induced by conventional ion-beam fabrication. Therefore, this expansion effect is a potential method to improve the ion-beam technology employed to fabricate complicated 3-dimensional structures requested in actively developing industrial fields, such as MEMS/NEMS. I. INTRODUCTION

In recent studies, the expansion effect has been observed in various crystals [1, 4-9], and the controllability along the vertical direction, a swelling height, was confirmed [10]. In contrast, no remarkable deformation of a crystalline silicon (c-Si) nano-structure along the lateral direction has been observed. Upon irradiating an ion beam on an amorphous silicon (a-Si) micro-structure, an irreversible deformation along the lateral direction has been observed [11, 12]. However, a high fluence, which is required for an irreversible deformation, would lead to the prolongation of the processing time compared with a deformation arising from the expansion effect. Furthermore, more studies are necessary to understand the expansion effect.

The deformation of a micro/nano-meter scale structure of c-Si along the lateral direction, which is induced by Kr-beam irradiation, was investigated. As the first step of the investigations, the present study focuses on the contributions of the fluence and the structure size. And the lateral deformation effect is discussed based on the crystalline-amorphous (c-a) phase change obtained from Raman spectroscopy and TEM observations. Furthermore, the present results will lead to a further understanding of the ion-beam induced expansion effect in crystalline materials.

II. EXPERIMENTAL

A. Preparation of initial nanostructures

Czochralski-grown (Cz-Si) p-type Si \{100\} samples, whose size and thickness is 1.5 × 1.5 cm² and 0.5 mm, were used in the present studies. In order to clean and remove any oxidized layer of the sample surface, all of the samples were sequentially washed in acetone, ultra-pure water, 18% buffered hydrofluoric acid (BHF) and ultra-pure water. An initial pattern of stripe structure was fabricated on the cleaned c-Si surface by using a 30 keV Ga⁺ FIB (QUANTA 3D 200i dual-beam system, FEI). An SEM image and a schematic picture of the cross section of the stripe structure are shown in Fig. 1. The length, L, and the height, H, of the stripe, which are defined in Fig. 1, are 10 μm and ~ 500 nm, respectively. Stripe structures, which consist a pile with four different widths of about 200, 300, 400 nm and 500 nm, were prepared. The formation of a damaged layer on the surface of a nano-structure, introduced by the FIB process, was reported in Ref. [13]. In order to remove this layer, processed samples were etched with 18% BHF for 12 minutes under an ultrasonic condition at room temperature. In order to relax any possible residual damage, such as point defects, we annealed samples in an argon ambient environment at atmospheric pressure by desktop lamp heating (MILA-3000, ULAVC). The condition of the annealing process was the same as that described in Ref. [14].
B. Modification of initial nanostructures by Kr-beam irradiation

In order to generate the lateral deformation in initial structures, Kr-\textsuperscript{+2} beams with an energy of 240 keV were implanted at room temperature with an incident angle of 5° so as to avoid any channeling effect. Kr beams were prepared by a 10-GHz NANOGAN, which is an ECR ion source installed at Kochi University of Technology [15]. The fluence of the Kr beam was 6, 8, 10, 30, and 50 \times 10^{13} ions/cm\textsuperscript{2}.

C. Evaluation of the defect distribution by SRIM

According to previous studies [10], the expansion effect shows a remarkable relation to damages induced by ion-beam implantation. In order to evaluate the spacial distribution of damages, SRIM-2008 [16] was used in a “detailed calculation with full damage cascades” mode for 10000 projectiles of the Kr-ion with kinetic energies of 240 keV. The calculated distributions of vacancies and ions are shown in Fig. 2 and Fig. 3, respectively. This calculation does not consider the self-annealing effect and the nonlinear effect, such as the interactions between defects. Figure 2 shows that the distribution of the vacancy is close to a Gaussian-like distribution. The distribution of vacancies covers the depth range from 0 nm to 300 nm, and shows its maximum at a depth of about 100 nm. As shown in Fig. 3, the range distribution of implanted Kr-ion also shows a Gaussian-like distribution, which is characterized by the projection range, 142.6 nm, and struggling, 44.9 nm. The calculated distribution shows that the major part of Kr-ions, \( \sim 75\% \), stops at a depth range between 100 nm and 190 nm. According to the above consideration, the region of interests, which would contribute to the expansion effect, is the range of depth between 0 nm and 200 nm.

D. Evaluation of the lateral deformation and c-a phase change of an irradiated Si sample

In order to obtain the lateral deformation of a stripe structure, FE-SEM (JSM-7401F, JEOL) was utilized to measure the geometrical size of the structures both before and after Kr-beam irradiation. The cross-section, which was formed by a cutting to cross the stripe pattern vertically, was observed. In the case of the deformation of crystalline materials induced by low-fluence ion-beam irradiation, it is expected that the evolutional transition of matrix structure, such as the growing features of the amorphous phase, plays an important role. In order to obtain information on the amorphization effect, a Raman spectrometer (HR 800 Horiba, 532 nm of laser) and a TEM (2100F, JEOL) were applied.

III. RESULTS AND DISCUSSIONS

A. Observation of stripe structures by SEM

Typical SEM images of stripe structures before and after Kr-beam irradiation are shown in Fig. 4. Figure 4(a) shows the cross section of a center pile in stripe structure at a given cutting plane before Kr-beam irradiation. The slope of sidewalls and curvature at the top edges is found in the observed cross sections. It is considered that those features arise from preparation processes of the initial structure. The cross section of the stripe structure
after Kr-beam irradiation is shown in Fig. 4(b) and the remarkable lateral deformation is identified as an increase in the width of a center pile, compared with Fig. 4(a). Therefore, the present study is on the deformation of stripe structure with a taper-shaped cross section.

B. Lateral deformation of the irradiated stripe structures

The widths of the center piles in stripe structures were measured at three different levels: higher (WH), middle (WM) and lower (WL) positions, which are defined in Fig. 4(a) according to consideration of the SRIM calculation in section II-D. Because of a curvature at the top edge, relatively large ambiguities were observed in WH. Therefore, the widths WM and WL are used in the following discussion. As the central value, the average of WM and WL is employed. The relation between the change in the widths, measured before and after Kr-beam irradiation, and the fluence of Kr-beam for structures with the width of 100 nm ∼ 200 nm is shown in Fig. 5. The width change, which is provided from one sample, is shown with no error bars. As shown in Fig. 5, the remarkable fluence dependence of the lateral deformation was observed for stripe structures. The width change increases up to a fluence of $8 \times 10^{13}$ ions/cm$^2$, and decreases to almost zero at a fluence of $5 \times 10^{14}$ ions/cm$^2$. To avoid any contribution of ambiguity in the initial structure size induced by the etching process, the lateral expansion rate was calculated, as shown in Fig. 6. Since sidewalls of a center pile have a slope with a tilt angle of 70 ∼ 80 degree, densities of implanted ions and defects changes along a lateral direction even at the same level. This effect would relax the intrinsic level dependence and gives obvious contribution for structures with small width. Therefore, the expansion rates obtained for WM and WL are averaged and the error bars are defined by those differences. Calculated lateral expansion rate shows similar behavior with the width change, and becomes maximum value of 30% at a fluence of $8 \sim 10 \times 10^{13}$ ions/cm$^2$.

In order to investigate the contribution of the structure size, the width change of the center pile in stripe structures was observed as a function of the width of the center pile at $8 \times 10^{13}$ ions/cm$^2$ and $1 \times 10^{14}$ ions/cm$^2$, at which a large lateral deformation effect was observed, as shown in Fig. 7. Figure 7(a) indicates that the width change becomes its maximum value, 55 nm, and decreases with the lateral size. A similar behavior is also found in Fig. 7(b).

C. Observation of Raman spectrum

To investigate the inner change of c-Si induced by the Kr-beam irradiation, a Raman spectrum was observed at the flat region near the patterned region. Observed evolutional behavior of the Raman spectrum with the fluence of the Kr-beam is shown in Fig. 8. A sharp peak at 520 cm$^{-1}$, which corresponds to c-Si, shrinks with the fluence. On the other hand, a peak at 510 cm$^{-1}$, which corresponds to a defective crystalline phase, appears in

http://www.sssj.org/ejssnt (J-Stage: http://www.jstage.jst.go.jp/browse/ejssnt/)
the spectrum for higher fluence. Also the broad peak placed at 480 cm$^{-1}$, which corresponds to a-Si, grows with the fluence, and becomes the dominant component in the spectrum for a fluence larger than $3 \times 10^{14}$ ions/cm$^2$.

The crystalline volume fraction of a-Si sample deduced from the Raman spectrum, $\phi_c$, was introduced in [17] as

$$\phi_c = \frac{I_{520} + I_{510}}{I_{520} + I_{510} + I_{480}},$$

where $I_i$ is the area under the Gaussian distribution, whose center is located at $i$. As a semi-quantitative index, the amorphization faction, $\phi_a$, is defined using $\phi_c$ as

$$\phi_a = \frac{I_{480}}{I_{520} + I_{510} + I_{480}}.$$

In Fig. 9, the amorphization fraction, calculated from the deconvoluted spectra obtained from three-peak fitting of the observed Raman spectrum, is shown as a function of fluence of the Kr-beam. The figure indicates that the c-a phase change proceeds continuously in the fluence range between $6 \times 10^{13}$ ions/cm$^2$ and $5 \times 10^{14}$ ions/cm$^2$. Considering Fig. 5, the range of the Kr-beam fluence, at which the lateral deformation effect shows remarkable fluence dependence, corresponds to the transitional range from the crystal phase to amorphous phase. The lateral deformation achieves the maximum at an amorphous fraction of about 85%. Also at higher fluence, the lateral deformation relaxes and returns to zero at an amorphous fraction of about 100%. As a result, Raman spectroscopy indicates that the amorphization process of c-Si has an obvious relation with the lateral deformation of the c-Si nano-structure.

**D. Observation by TEM**

Figure 10 shows cross-sectional TEM images of the stripe structure irradiated by a Kr beam with three different fluences. In this figure, an amorphous layer is clearly recognized in the top and sidewalls of the stripe structure, and is separated from the crystalline region by an interface. The thickness of the amorphous layer grows with the Kr-beam fluence and reaches to 270 nm at the top of the center pile and 249 nm at the flat region for a fluence of $5 \times 10^{14}$ ions/cm$^2$. This result indicates that the depth region of interest, 0 - 200 nm, mentioned in II D, is completely amorphized for higher fluence. The growing nature of the amorphous layer is consistent with the increase in the amorphous fraction, which was obtained from the Raman spectra. The figure also shows the differences in the thickness of the amorphous layer at the right and left sidewalls of the stripe structure. The tilt angle of Kr-beam irradiation from the normal of Si-surface would cause the asymmetric feature. In section III C, observed Raman spectra indicated the importance of the c-a phase change in order to understand the lateral deformation effect on nano-structure. In the case of heavy-ion irradiation at low temperature, the c-a phase change proceeds through the overlap of the isolated damaged region induced by ion-beam irradiation, and shows a heterogeneous nature. Therefore, the amorphization induced by Kr-ion irradiation at room temperature is expected to be heterogeneous. Also, observed lateral deformation indicates structure size dependence, as described in section III B. To investigate the heterogeneous features in and around the amorphous region and contributions of the lateral size, high-resolution TEM images of center piles were observed for two structures with different lateral sizes, and shown.
The spectrum for each fluence is vertically displaced for clarity. Spectra for a virgin crystal Si is also shown for reference. The fluence range for the lateral deformation, is significantly lower than that for irreversible deformation, which was observed in a-Si micro/nano-structure [11, 12]. The irreversible deformation for amorphous material is called plastic deformation, and is successfully explained by a viscoelastic model proposed by Trinkaus and Ryaznov [19]. And, the presently observed deformation is promoted for structures with small lateral size, and suppressed for those with large lateral size. The size effect on plastic deformation is caused to a nonhydrostatic stress distribution by surface curvature. Because initial phases and/or morphological shapes as well as irradiation parameters are different, it is difficult to apply those previous models to explain the presently observed lateral deformation. In the present studies, initial structures are in the crystalline phase as described in section III D. The amorphous/crystalline pockets and internal stress were observed in TEM images for stripe structures, in which a remarkable lateral deformation was observed. Therefore, the fluence dependence of the lateral deformation is considered by means of the amorphous/crystalline pockets.

**E. Mechanism of lateral deformation induced by the low-fluence Kr-beam irradiation**

The sputtering effect is another important contribution to cause the lateral deformation. Considering the sputtering rate and its incident angle dependence, which are evaluated by SRIM, the contribution of sputtering effect to the lateral deformation under the present irradiation condition is calculated to be less than 0.64 nm even at the maximum fluence of $5 \times 10^{14}$ ions/cm$^2$. Therefore, the sputtering effect is not considered in the following argument.

The presently observed deformation, which was induced by Kr-beam irradiation with low fluence, is compared with the previously observed deformation. The growing and shrinking of the lateral deformation was observed in the fluence range, within which the crystalline phase continuously changes to the amorphous phase. The effective fluence range for the lateral deformation, is significantly lower than that for irreversible deformation, which was observed in a-Si micro/nano-structure [11, 12]. The irreversible deformation for amorphous material is called plastic deformation, and is successfully explained by a viscoelastic model proposed by Trinkaus and Ryaznov [19]. And, the presently observed deformation is promoted for structures with small lateral size, and suppressed for those with large lateral size. The size effect on plastic deformation was observed for spherical SiO$_2$ colloid [20] and ascribed to a nonhydrostatic stress distribution by surface curvature. Because initial phases and/or morphological shapes as well as irradiation parameters are different, it is difficult to apply those previous models to explain the presently observed lateral deformation. In the present studies, initial structures are in the crystalline phase as described in section III D. The amorphous/crystalline pockets and internal stress were observed in TEM images for stripe structures, in which a remarkable lateral deformation was observed. Therefore, the fluence dependence of the lateral deformation is considered by means of the amorphous/crystalline pockets.
FIG. 10. Cross-sectional TEM images of Stripe structures irradiated by a Kr beam with fluences of (a) $8 \times 10^{13}$, (b) $1 \times 10^{14}$ and (c) $5 \times 10^{14}$ ions/cm$^2$.

FIG. 11. TEM images of stripe structures with the width of the center pile of $\sim 100$ nm, irradiated with a fluence of $1 \times 10^{14}$ ions/cm$^2$; (a) cross-sectional image; (b), (c) are images of higher resolution. The rectangles in (a) and (b) indicate the observed regions for higher resolution. Amorphous pockets and crystalline pockets are highlighted by white circles and black circles, respectively. (d) Fourier transform of (c).

The cascade localization induced bias (CLIB) model, proposed by Yoshiie et al. [21] to explain the behaviors of defects in the lattice system, indicates that defects induced in the Si lattice by Kr-beam irradiation would be absorbed by boundaries between amorphous/crystalline pockets and their surroundings. This absorption stimulates the growth of amorphous pockets and shrinkage of the crystalline pockets. Also, when amorphous pockets grow to overlap with others, amorphous pockets combine and contributions of boundaries to absorb defects are suppresses. Based on this idea, the fluence dependence can be qualitatively understood as follows. In the case of lower fluence, amorphous pockets are produced and grow to promote a heterogeneous nature with the fluence of Kr beam.

Then the internal stress, which promotes the expansion effect, increases. On the other hand, in the case of higher fluence, amorphous pockets start combining with others with increasing the fluence of Kr beam. Then the internal stress decreases.

Considering observed TEM images, the following naive model is a possible candidate to explain the contribution of lateral size to the lateral deformation. In the case of a smaller lateral size, the crystalline region between two interfaces in the center pile reduces, and the major part of the center pile is occupied by the amorphous region. Therefore, contributions of stress induced by the heterogeneous nature would become obvious in the whole region between the interfaces in the left and right sidewall, and promote an expansion along the lateral direction. In contrast, in the case of the larger lateral size, the contribu-
tion of the crystalline region, which tends to keep its form, becomes prior. Therefore, the lateral deformation effect would be suppressed by the crystalline region compared with structures of smaller lateral size.

IV. CONCLUSIONS

In conclusions, a deformation of taper-shaped Si structures along the lateral direction has been successfully achieved firstly by irradiating Kr beam of 240 keV. The observed results have shown that the lateral deformation depends on the lateral size of stripe structure as well as the fluence of Kr beam. The typical fluence of a 240 keV Kr-beam employed to provide lateral deformation is about $1 \times 10^{14}$ ions/cm$^2$. This fluence is much lower than the typical fluence of ion beams, which is needed to provide plastic deformation in amorphous materials. The amorphous/crystalline pockets, which were observed with stress in the lattice structure, can provide a consistent qualitative explanation for observed lateral deformation and its fluence dependence. The suppression effect on the lateral deformation, which would be originated from crystalline region between two interfaces in the center pile, provides a possible explanation for the structure size dependence. However, further investigations are needed to confirm the reliability of this idea. In addition, the contributions of irradiation energy and ion species will be performed in next studies.
