The recent paradigm for managing acromegaly includes microsurgery or endoscopic surgery (transsphenoidal surgery or craniotomy), pharmacological therapy (somatostatin analogue, growth hormone-receptor antagonist, dopamine receptor agonists) and radiosurgery which reverse excessive growth hormone (GH) secretion, and shrink or ablate tumors without compromising normal pituitary function. Maximal control of GH level, reduction of systemic complications and mortality, control of tumor growth, preservation of pituitary function, and extension of life expectancy are the aims of disease management. But these aims are difficult to achieve in most patients with macroadenomas, especially invasive tumors. The main reason is it is difficult to totally resect large invasive tumors, hence optimal and long-term biochemical control is seldom achieved.

Transsphenoidal surgery has been accepted as first-line therapy for GH-secreting pituitary adenoma [1]. Surgical results depend on tumor size, tumor invasion, and preoperative GH levels [2-5].

The somatostatin analogue, octreotide and its long-acting preparation has been used to treat acromegaly for the past two decades. A review of the literature shows that long-acting octreotide reduces GH level, tumor size, and relieves systemic symptoms [6-9]. Nevertheless long-term use of somatostatin analogs may be limited due to the cost [10], thus short-term presurgical use of long-acting octreotide may be cost-effective. Whether or not presurgical medical treatment improves the remission rates of invasive mac-
roadenomas and boosts the final cure rate is unclear [11-15]. In assessing the historical experience, analysis is challenging because most studies are retrospective. The lack of direct comparisons, reliance on single GH values, a large range of octreotide doses utilized, and relatively small numbers of patients, are among the confounding factors [10, 13, 16]. Besides, the different proportion of patients with different tumor characters (size and invasiveness) makes these conclusions less instructive (Table 1).

Therefore, we designed this prospective comparative study. Thirty-nine acomegaly patients, all with invasive macroadenomas, from January 2005 to June 2006 in our center, were randomly divided into an experimental group (n=19) and a control group (n=20). Patients in the experimental group received a 3-month-course of long-acting octreotide (drug pretreatment, 20 mg i.m. every 28 days, for 3 months) before transsphenoidal surgery; the other group underwent surgery directly. Imaging and endocrine results were analyzed for the two groups, so as to evaluate therapeutic effects of long-acting octreotide pretreatment on tumor size reduction, short- and long-term postoperative GH and type-1 insulin like growth factor (IGF-1) levels in patients with GH-secreting invasive pituitary macroadenomas. This was an open, prospective, comparative, randomized clinical study. Written informed consent was obtained from each patient before inclusion and the Declaration of Helsinki was followed throughout the study. The study was approved by the hospital Ethics Committee before commencing.

**Materials and Methods**

**Patients (Table 2)**

All patients were adults over 18 years old, and the diagnosis was based on clinical features of acromegaly (typically, carpal tunnel syndrome, acroparesthesia, hyperhidrosis, arthralgias, debility, sleep apnea, visual field defects, soft tissue swelling, lumbodorsal pain, and headache) [17]. Nadir GH levels after oral glucose tolerance test (OGTT) were >1 µg/L, and IGF-1 levels were elevated for age and gender adjusted ranges, and pituitary magnetic resonance imaging (MRI) showed pituitary tumors >10 mm in diameter, which invaded at least one direction to suprasellar, parasellar or infero-sellar regions, and according to Hardy-Knosp grade & stage standard [18], the tumors were ≥ III in grade or C to E in stage. We assigned it ≥ 3 in this situation, and ≤ 2 when the tumors were ≤ II in grade and 0 to B in stage. All patients planned to undergo transsphenoidal surgery, and had no history of prior surgery, radiotherapy or medical treatment. They were randomly divided into two groups. The experimental group comprised

19 patients with pituitary macroadenoma (8 women, 11 men; mean age 39.2±10.8 years) Acromegaly developed over a period of 6.5±4.6 years prior to diagnosis. Follow-up was 28.8±13.4 months after surgery. The control group comprised 20 patients with acromegaly (13 women, 7 men; mean age 44.1±10.5 years). Acromegaly developed over a period of 6.4±3.9 years prior to diagnosis. Follow-up was 26.6±4.2 months after surgery. All operations were performed by a single experienced surgeon in our center.

**Endocrine evaluation**

All patients underwent endocrine examinations before and after surgery, and additional exams before and after drug pretreatment were added to the experimental group. Endocrine testing included nadir GH after OGTT (the lowest GH levels measure at 0, 30, 60, 90, and 180 min after 75 g oral glucose) and measuring serum IGF-1 levels. GH level measurement was performed using time-resolved fluoroimmunooassay (PerkinElmer Life and Analytical Sciences, Turku, Finland); IGF-1 was measured by DSL-10-2800 ACTIVE Non-Extraction IGF-1 ELISA (Diagnostic Systems Laboratories, Inc., Webster, TX). The normal IGF-1 concentration adjusted by age and gender in Chinese population was as follows (ng/mL): 21~30 y, male 116~329, female 117~358; 31~40 y, male 109~284, female 115~307; 41~50 y, male 94~252, female 101~267; 51~60 y, male 87~225, female 81~238; 61~70 y, male 75~212, female 69~200; 71~80 y, male 64~188, female 59~177; 81 y+, male 60~171, female 50~160. The endocrine remission criteria for acromegaly were nadir GH after OGTT less than 1µg/L and IGF-1 levels within the normal ranges as matched by age and gender [19-21].

**Tumor size evaluation**

All patients underwent pituitary MRI examinations with spin-echo sequence T1-weighted MRI, with a 3.0-T whole-body MRI scanner (General Electric Medical Systems, Milwaukee, WI) before and after i.v. gadolinium administration. Because tumors were irregular in shape, we transferred the adopted DICOM data sets into the Dextroscope workstation (Dextroscope, Volume Interactions Pte. Ltd., Singapore) to generate a 3-D model, to calculate the precise tumor size.

**Drug pretreatment**

All patients underwent the tolerance and sensitivity tests to the drug. Short-acting octreotide (Sandostatin, Novartis Pharma AG, Basel, Switzerland) 0.1 mg hypodermic injection, 3 times (8 a.m., 4 p.m., and 12 p.m.), evaluate GH level before the first injection and at 8 A.M. the next day, if the second GH level declined more than 20%, the patient was considered to be sensitive to the drug [22]. Patients were randomly divided into the two groups as mentioned above.

The experimental group received a 3-month-course of long-acting octreotide (Novartis Pharma AG, Basel, Switzerland) pretreatment (20 mg i.m. every 28 days, for 3 months) before transsphenoidal surgery. Abdominal ultrasound was performed to screen for cholecystolithiasis during medication. Nadir GH levels after OGTT, IGF-1 levels and pituitary MRI were performed before and after drug pretreatment to evaluate the effects of medication. At surgery, the tumor texture was classified as soft, soft-firm, firm, firm-hard, or hard; the degree of tumor invasion to surrounding structures was classified as none, local, or extensive.

**Remission criteria and follow-up**

After surgery, we routinely transferred the patients to the Endocrine Department of our hospital for further medical treatment. Endocrine remission criteria for acromegaly included nadir GH after OGTT <1 µg/L and IGF-1 within the normal range matched by age and gender [19, 20, 23]. All patients underwent nadir GH and IGF-1 level evaluation, and pituitary MRI examination at 3 months, 6 months, 1 year, and annual follow-up. None of the patients withdrew from the study or was lost to follow-up during the study period. Four patients in experimental group and 7 in control group were required to receive a gamma-knife radiotherapy about 6 months after unsuccessful surgery.

**Statistics**

When data distribution was normal, mean±SE was used, otherwise median values should be calculated as M (P25–P75), but we still used mean±SE, to make a more uniform comparison and an easier understanding. Normal distribution was tested by the Shapiro-Wilk W test. Between-group comparisons were analyzed by t-test when data distribution was continuous and normal or by Wilcoxon rank-sum (Mann-Whitney) test when data distribution was continuous but abnormal. Incontinuous data were analyzed by Pearson Chi-square test when n ≥ 40 or by Fisher’s exact method when n<40. Ordered categories were analyzed by Cochran-
reach statistical significance at 6 months after surgery and during long-term follow-up ($P_{GH}=0.082$ and 0.27).

c. IGF-1 levels: In the experimental group, IGF-1 levels were $884\pm212$, $340\pm179$, $324\pm188$, and $327\pm145\ \mu\text{g/L}$, after drug-pretreatment, and at 3 months, 6 months after surgery and long-term follow-up, respectively. Percentage of patients with normal IGF-1 matched by age and gender was 42.1% (8/19), 47.4% (9/19), and 36.8% (7/19), at 3 months, 6 months after surgery and long-term follow-up respectively. In the control group, IGF-1 levels were $505\pm190$, $474\pm194$, and $431\pm166\ \mu\text{g/L}$, at 3 months, 6 months after surgery, and long-term follow-up, respectively. Percentage of patients with normal IGF-1 matched by age and gender was 10% (2/20), 20% (4/20) and 20% (4/20), at 3 months, 6 months after surgery, and long-term follow-up respectively. IGF-1 levels at 3 months, 6 months after surgery, and long-term follow-up reached statistical significance ($P_{IGF-1}=0.0085$, 0.019, 0.048). Percentage of patients with normal IGF-1 matched by age and gender reached statistical significance at 3 months follow-up ($P=0.031$), while the data did not achieve statistical significance at 6 months and at long-term follow-up ($P=0.096$ and 0.30).

d. Remission rates: Remission rate (nadir GH <1 µg/L and normal IGF-1 level) of the experimental group was higher than the control group at 3 and 6 months follow-up [31.6% (6/19) vs 5% (1/20), 42.1% (8/19) vs 10% (2/20), $P=0.044$ and 0.031], but showed no advantage at long-term follow-up [31.6% (6/19) vs 10% (2/20), $P=0.13$].

**Symptomatic relief of the experimental group after drug pretreatment** (Fig. 1 and Table 4)

Typical symptoms of acromegaly including carpal tunnel syndrome, acroparesthesia, hyperhidrosis,
Presurgical treatment in acromegaly

...octreotide treatment in the experimental group, which contributed to reduce the risk of surgery. Meanwhile, these improvements also could be seen in both experimental group and control group after surgery. While compared with the control group, the experimental group did not show any significant advantage either in the level of blood glucose or blood pressure, and the number of patients with IGT (impaired glucose tolerance) or DM (diabetes mellitus) or HBP (high blood pressure), during the follow-up period (respectively, at 3 and 6 months after surgery, and at the last investigation). There may have been some reasons for this discrepancy such as: 1) cohort size of this study was too small to reach statistical significance; 2) DM and HBP are complex diseases and may be caused by other factors besides acromegaly.

arthralgias, headache, debility, sleep apnea, soft tissue swelling, and lumbodorsal pain were graded as none, slight, midrange, or severe, and were assigned as 0, 1, 2, or 3 respectively. Scores of the experimental group before and after pretreatment were (1.2±0.7) / (0.5±0.5) \( [P=0.0028] \), (1.2±0.6) / (0.4±0.5) \( [P=0.0001] \), (1.5±0.8) / (0.6±0.5) \( [P=0.0004] \), (1.2±0.7) / (0.4±0.6) \( [P=0.0007] \), (1.0±0.7) / (0.5±0.5) \( [P=0.016] \), (1.1±0.6) / (0.6±0.7) \( [P=0.049] \), (1.2±0.7) / (0.3±0.5) \( [P=0.0001] \), (1.3±0.8) / (0.5±0.6) \( [P=0.0031] \), (1.1±0.5) / (0.3±0.5) \( [P=0.0001] \). Cardiac ejection fraction was 56.8±3.7% and 62.1±3.4% before and after pretreatment \( (P=0.0060) \). These results indicated that medical pretreatment relieved the typical symptoms of acromegaly. As indicated in Table 4, both the glucose tolerance and high blood pressure were significantly improved after octreotide treatment in the experimental group, which contributed to reduce the risk of surgery. Meanwhile, these improvements also could be seen in both experimental group and control group after surgery. While compared with the control group, the experimental group did not show any significant advantage either in the level of blood glucose or blood pressure, and the number of patients with IGT (impaired glucose tolerance) or DM (diabetes mellitus) or HBP (high blood pressure), during the follow-up period (respectively, at 3 and 6 months after surgery, and at the last investigation). There may have been some reasons for this discrepancy such as: 1) cohort size of this study was too small to reach statistical significance; 2) DM and HBP are complex diseases and may be caused by other factors besides acromegaly.

*Significance of difference between groups [Diag / Diag, PO3 / PO3, PO6 / PO6, LI / LI]. †p<0.05 versus diagnosis.

Fig. 1 Presurgical octreotide treatment improved patients’ symptoms such as sleep apnea and soft tissue swelling, and improved patients’ cardiac function such as Left Ventricular Ejection Fraction (LVEF) \( [P=0.0060] \), Wilcoxon rank-sum (Mann-Whitney) test. The degree of symptom was graded as none, slight, midrange, or severe, and was assigned as 0, 1, 2, or 3 respectively.
>75%, 50%~75%, 25%~50%, or 0~25% tumor size reduction was 2, 5, 5, and 7, respectively. The mean reduction was 37.4±30.9%.

Comparison of tumor texture, invasion and resection rate during surgery

Tumor texture was classified as soft, soft-firm, firm, firm-hard, or hard, and calculated as 0, 1 to 4, respectively. The degree of tumor invasion to surrounding structures was classified as none, local, extensive, and calculated as 0, 1 to 2, respectively. All evaluations were performed by one experienced surgeon. Score of tumor texture and invasion degree was 1.5±1.0 and 0.94±0.64 in the experimental group, while the parameter for the control group was 0.8±0.5 and 1.5±0.6. Differences between the two groups were significant (P=0.037 and 0.0084) (Fig. 4). These data indicated the tumor texture was harder (Fig. 5) but the invasion was less extensive in the experimental group. Total resection rate

Side-effects of drug pretreatment

All patients in the experimental group underwent routine examination including blood chemistry, liver and renal function, serum electrolyte, electrocardiogram, and abdominal ultrasound. No obvious dysfunctions were detected. There were no significant changes of transsphenoidal surgery complications such as diabetes insipidus, CSF leakage, visual deterioration, hypothyroidism, electrolyte disturbance, liver dysfunction or cardiovascular complications between the two groups, except that the incidence of CSF leak was lower in the experimental group (2/19 vs 9/20, P=0.031).

Tumor size reduction after drug pretreatment (Figs. 2, 3)

Baseline tumor size was not different in the experimental and control groups, 7893±6450 and 7616±6163 mm$^3$ (P=0.79). After pretreatment tumor size of the experimental group was significantly lower, 4794±4682 mm$^3$ (P=0.032). The number of patients exhibiting

Fig. 2  Presurgical octreotide treatment reduced tumor volumes.

Fig. 3  Enhanced head MRI of a patient with a Hardy-Knosp Grade 3 adenoma before (A), after (B) octreotide treatment, and after surgery (C).
Presurgical treatment in acromegaly

The experimental and the control group on the total resection rate based on the Hardy-Knosp grading. In fact, it was almost impossible to totally resect a tumor of Hardy-Knosp grade 4 and 5. Within the experimental group, we further divided the 19 patients into two subgroups; one was those whose Hardy-Knosp grading decreased to ≤ 2 (n=9) after drug treatment, and the other was those whose Hardy-Knosp grading is still ≥ 3 (n=10) after drug treatment. There were 8 patients in the first group, but only one patient in the second group got a total resection via surgery as assessed by early postoperative MRI ($P=0.001$) (Table 5). This result suggested that the main reason for the high total resection rates in the experimental group was the drug pretreatment made some of the tumors less invasive.

of Hardy-Knosp Grade 2 (post-drugs) adenoma was 88.9% in the experimental group. No such adenoma was included in the control group. The total resection rates of Hardy-Knosp Grade 3 adenoma were 25% and 20% in the experimental (post-drugs) and the control groups, respectively. Total resection rates of Hardy-Knosp Grade 4 adenoma were 0 and 25% in the experimental and the control groups, respectively. (Only one patient in control group got a total resection. Although she had a stage IV adenoma diffusely destroying the sellar floor, the tumor did not invade into the cavernous sinus and was totally removed with the help of neuronavigation.) Total resection rates of Hardy-Knosp Grade 5 adenoma were 0 in both groups. These data showed that there was no significant difference between the experimental and the control group on the total resection rate based on the Hardy-Knosp grading. In fact, it was almost impossible to totally resect a tumor of Hardy-Knosp grade 4 and 5. Within the experimental group, we further divided the 19 patients into two subgroups; one was those whose Hardy-Knosp grading decreased to ≤ 2 (n=9) after drug treatment, and the other was those whose Hardy-Knosp grading is still ≥ 3 (n=10) after drug treatment. There were 8 patients in the first group, but only one patient in the second group got a total resection via surgery as assessed by early postoperative MRI ($P=0.001$) (Table 5). This result suggested that the main reason for the high total resection rates in the experimental group was the drug pretreatment made some of the tumors less invasive.

**Fig. 4** Differences of tumor texture and degrees of tumor invasion to surrounding structures were significant between groups. (Tumor texture was classified as soft, soft-firm, firm, firm-hard, hard, and calculated as 0, 1 to 4 respectively, in the left column. The degree of tumor invasion to surrounding structures was classified as none, local, extensive, and calculated as 0, 1 to 2 respectively, in the right column. Open column and closed column stand for the experimental and control group, respectively).

**Fig. 5** Representative histological pictures of adenomas from the control (A) and experimental (B) groups. The left picture showed the tumor was rich in cells, while the right picture showed the tumor had more intra-tumoral fibrosis and cells arrangement inside it seemed more compacted.
In our study, the use of presurgical long-acting octreotide helped to increase the total resection rates and short-term remission rates (both GH and IGF-1 normalized) of the experimental group. We suppose the main reason was the drug pretreatment decreased tumor invasiveness and made it easier to be removed by surgery, as indicated by Fig. 4 and Table 5. However, during long-term follow-up, remission rates of the experimental group showed no advantage, likely due to the facts that all the cases in our study were patients with invasive macroadenomas. Some residual adenomas, especially when presurgical long-acting octreotide failed to reduce tumor invasiveness (Hardy-Knosp grading still ≥ 3), recurred after 6 months follow-up, with elevated nadir GH and IGF-1 levels. This suggests that patients in the above situation should be observed closely, and receive early pharmacotherapy or radiotherapy to control adenoma recurrence.

Although transphenoidal surgery is commonly considered a procedure with low risk, most acromegaly patients have several major complications, including cardio- and cerebrovascular disease, respiratory dysfunction, hyperglycemia, and swelling of soft tissue, leading to intubation difficulty and other anesthetic risks [30]. All the patients in this series were first diagnosed, and had a long acromegaly history, without adequate treatment. In our study, presurgical long-acting octreotide decreases tumor volume [15, 16, 25-29], and so presurgical long-acting octreotide should have greater therapeutic value, if the drug relieves the macroadenoma invasiveness [24].

In our study, the use of presurgical long-acting octreotide helped to increase the total resection rates and short-term remission rates (both GH and IGF-1 normalized) of the experimental group. We suppose the main reason was the drug pretreatment decreased tumor invasiveness and made it easier to be removed by surgery, as indicated by Fig. 4 and Table 5. However, during long-term follow-up, remission rates of the experimental group showed no advantage, likely due to the facts that all the cases in our study were patients with invasive macroadenomas. Some residual adenomas, especially when presurgical long-acting octreotide failed to reduce tumor invasiveness (Hardy-Knosp grading still ≥ 3), recurred after 6 months follow-up, with elevated nadir GH and IGF-1 levels. This suggests that patients in the above situation should be observed closely, and receive early pharmacotherapy or radiotherapy to control adenoma recurrence.

* We assigned the Hardy-Knosp grading ≤ 2 when the tumors were ≤ II in grade and 0 to B in stage; 3 when the tumors were ≤ III in grade with 0 to C in stage, or I to II in grade with C in stage; 4 when the tumors were ≤ IV in grade with 0 to D in stage, or I to III in grade with D in stage; and 5 when the tumors were ≤ V in grade or E in stage.

** TR stands for the number of patients achieved a total resection; n stands for the total number of patients in each subgroup; % is the percentage.

As indicated in Table 5, the two subgroups (≤ 2 and ≥ 3) did not show a similar distribution in Hardy-Knosp grading (3.3±0.7 vs 4.3±0.7, P=0.0089) before the octreotide treatment, and the subgroup in which the Hardy-Knosp Grading declined from 3 to 2 got the most merits from the presurgical treatment. This indicated that subgroup ≤ 2 showed a less invasive degree than subgroup ≥ 3, and was relatively easier to change from a less invasive adenoma to a non-invasive one after using drugs. As a result, a higher rate of total resection of the adenomas (88.9%) was achieved in this group (P=0.001) (Fig. 3), which may lead to a lower recurrence in follow-up. This suggested that the status of pre-drug invasiveness was a crucial factor for the consequent surgical treatment outcome.

Discussion

According to the extensive surgical experience in our center [3], all microadenomas, and some macroadenomas with distinct capsules and no significant invasion can be readily removed via transphenoidal surgery. On the other hand, low resection rates of the invasive macroadenomas are reported [5, 24]. As indicated by several reports, presurgical long-acting octreotide decreases tumor volume [15, 16, 25-29], and so presurgical long-acting octreotide should have greater therapeutic value, if the drug relieves the macroadenoma invasiveness [24].

In our study, the use of presurgical long-acting octreotide helped to increase the total resection rates and short-term remission rates (both GH and IGF-1 normalized) of the experimental group. We suppose the main reason was the drug pretreatment decreased tumor invasiveness and made it easier to be removed by surgery, as indicated by Fig. 4 and Table 5. However, during long-term follow-up, remission rates of the experimental group showed no advantage, likely due to the facts that all the cases in our study were patients with invasive macroadenomas. Some residual adenomas, especially when presurgical long-acting octreotide failed to reduce tumor invasiveness (Hardy-Knosp grading still ≥ 3), recurred after 6 months follow-up, with elevated nadir GH and IGF-1 levels. This suggests that patients in the above situation should be observed closely, and receive early pharmacotherapy or radiotherapy to control adenoma recurrence.

Although transphenoidal surgery is commonly considered a procedure with low risk, most acromegaly patients have several major complications, including cardio- and cerebrovascular disease, respiratory dysfunction, hyperglycemia, and swelling of soft tissue, leading to intubation difficulty and other anesthetic risks [30]. All the patients in this series were first diagnosed, and had a long acromegaly history, without adequate treatment. In our study, presurgical long-acting
octreotide ameliorated clinical symptoms, including carpal tunnel syndrome, acroparesthesia, hyperhidrosis, arthralgias, headache, debility, sleep apnea, soft tissue swelling, lumbodorsal pain, and also reduced glucose level and blood pressure level. This would be helpful for intubation and anesthesia, and reduce complication rates, especially for acromegaly patients with cardiac insufficiency.

Recently, owing to the application of neuronavigation, neuroendoscope, and intraoperative MRI in transsphenoidal surgery, surgical resection of pituitary adenomas has improved greatly. Patients in this series were recruited during a period of 18 months, and underwent the same surgical procedure performed by the same senior surgeon, thus decreasing the variability of the procedure due to new technology or different surgeons. Therefore, our randomized and prospective study can minimize this potential bias.

However, the total case number of our study is less than others and the follow-up time is shorter. Therefore, a controlled multicenter long term study would help resolve this important management question for acromegaly.

Conclusions

Presurgical long-acting octreotide treatment effectively reduced tumor volume and invasion, and decreased postoperative GH and IGF-1 levels, enabling improved early remission rates of transsphenoidal surgery, but did not boost the long-term curative rate. When presurgical long-acting octreotide fails to reduce tumor invasiveness, patients should be evaluated 6 months postoperatively for reoperation, pharmacotherapy or radiotherapy.
