THE SCREENING of newborns for congenital hypothyroidism (CH) is now routinely conducted in many countries and aims towards the early detection and treatment of one of the most common preventable causes of intellectual retardation [1–4]. The most common strategy for newborn screening is a primary TSH with backup T4 strategy, which involves an initial TSH measurement, followed by T4 measurement if high TSH levels are detected [3, 4]. The rationale for this strategy is based on the fact that most CH cases have a thyroidal origin (CH-T), such as thyroid gland dysgenesis or thyroid hormone synthesis defects [5].

Kanagawa Prefecture in Japan, however, has adopted a strategy of simultaneous measurement of free T4 (FT4) and TSH levels in all newborns, which is referred to as a primary FT4 and TSH strategy. Screening of FT4 levels has enabled the detection of a significant number of cases of CH of central origin (CH-C), the incidence of which has been estimated to be 1 in 30,833 live births in Kanagawa Prefecture [6]. Another possible advantage of screening using FT4 measurement is that it enables the detection of transient CH-C, which usually develops in newborns with hyperthyroid mothers [7–11]. Although hypothyroidism under these conditions may be self-limiting, it can lead to intellectual disabilities if it is not detected and treated [11]. In addition, FT4 measurement may enable the identification of newborns with CH-T with delayed TSH elevation—found mainly in premature and/or low birth weight (LBW) newborns—who may not be identified by a primary TSH strategy [2, 4, 12–14].

In the present study, we aimed to evaluate the effi-
cacy of screening by using FT4 measurement, when transient CH-C and CH-T with delayed TSH elevation are included as target entities in the screening system.

Materials and Methods

This study has been approved by the Institutional Review Board of Kanagawa Children’s Medical Center and followed the World Medical Association Declaration of Helsinki regarding ethical conduct of research involving human subjects.

Newborn screening system

The details of our screening methods were described in a previous report [6]. In brief, the screening procedure is based on the determination of TSH and FT4 levels in dried blood spots obtained 4–7 days (median, 5 days) after birth. Newborns with high TSH levels (≥30 µIU/mL of serum) are immediately referred to one of the regional pediatric endocrine units. A second filter paper sampling is requested in those with borderline TSH levels (15–30 µIU/mL of serum) or low FT4 levels (<0.7 ng/dL [9.0 pmol/L] of serum). If the results again indicate high TSH level (≥15 µIU/mL) or low FT4 level (<0.7 ng/dL), the newborn is referred for a thorough evaluation. In the current study, TSH levels in filter paper samples were determined using the enzyme-linked immunosorbent assay with mouse monoclonal antihuman TSH antibodies (Eiken Chemical Co. Ltd., Tochigi, Japan), whereas FT4 levels in filter paper samples were determined using ENZAPLATE N-FT4 (Siemens Healthcare Diagnostics K.K., Tokyo, Japan).

Data collection

The first step in the data collection was conducting a survey regarding CH-C, as has been described previously [6]. In brief, through 2008 and 2009, a questionnaire was sent to all 139 hospitals with a pediatric section in Kanagawa Prefecture requesting them to report the number of and clinical data regarding the CH-C cases born between 1999 and 2008.

The next step involved searching through the database compiled by the Neonatal Mass-screening Committee (NMC) of the Kanagawa Prefecture Medical Association (KPMA). This database contained all the screening results and details of the first-line investigation performed at the pediatric endocrine units for screening-positive patients. Cases diagnosed as either CH-C or transient CH-C were identified for further analysis. Transient CH-C was defined as a case in which CH-C was once suspected because the FT4 level was <0.7 ng/dL in both the first and second samples and in which the administration of l-thyroxine was performed until recovery of thyroid function. In addition, we identified CH-T cases with delayed TSH elevation, defined as CH-T cases in whom both FT4 level <0.7 ng/dL (positive result) and TSH level <15 µIU/mL (negative result) were recorded at least once during screening.

Results

CH-C

As we previously reported [6], 24 CH-C patients who had been born in Kanagawa Prefecture between 1999 and 2008 were identified, among whom 13 patients had a positive screening result for FT4 level (<0.7 ng/dL) (Table 1). Of these 13 patients, 12 were identified solely through newborn screening, whereas the other patient with hypopituitarism was diagnosed after presenting with a shock state along with the measurement of a positive FT4 level result (0.58 ng/dL) during screening.

Transient CH-C

Review of the NMC-KPMA database revealed that out of the 740,003 newborns screened between 1999 and 2008, 113 were suspected to have CH-C because of the measurement of an FT4 level (<0.7 ng/dL) (Table 1). Of these 113 patients, 5 were ultimately diagnosed with transient CH-C. The other patients were diagnosed with CH-C (including indefinite cases; n = 20), low FT4 due to prematurity (n = 23), critical illness (n = 26), thyroxine-binding globulin deficiency (n = 12), and undetermined condition (n = 27). All 5 patients diagnosed with transient CH-C were born to mothers with Graves’ disease. Table 2 provides detailed data regarding each patient.

CH-T with delayed TSH elevation

Of the 113 cases in the NMC-KPMA database in which CH-C was suspected, 6 were identified as CH-T with delayed TSH elevation. Table 3 summarizes their background data and thyroid function test results both at screening and during the thorough evaluation. All 6 patients were treated in the neonatal intensive care unit (NICU) at the time of screening because of various indications. Four patients were either preterm newborns with a gestational age of <37 weeks or LBW newborns.
Newborn screening with FT4 measurement

Efficacy of the screening system involving FT4 level measurement

The use of the FT4 screening system allowed for the identification of 24 true-positive cases, yielding a detection rate of 24/740,003 or 1 in 30,833 births.

Discussion

Transient CH-C occurs in infants born to mothers who develop hyperthyroidism during their pregnancy because of inadequately treated Graves’ disease [7-11]. As shown in Table 2, 5 cases of transient CH-C were identified by the measurement of low FT4 levels through newborn screening. To our knowledge, this is the first systematic audit of transient CH-C patients identified through FT4 screening.

As observed in our patients, FT4 levels in transient CH-C may be markedly low [7-11], and hypothyroidism in transient CH-C may persist for more than 1 year [8, 11]. In addition, the transition from CH-C to CH-T due to thyroid disintegration has been reported, similar to that noted in patient 14 in the present study [10]. Accordingly, failure to identify and treat this condition will likely result in serious intellectual disabilities [11]. Of the 5 patients with transient CH-C, 4 (patients 14, 16, 17, and 18 in Table 2) did not undergo thyroid function evaluation until the screening results had been reported. In other words, these 4 patients may have been overlooked if they had not undergone FT4 screening. It is of particular interest that in 3 patients (patients 14, 17, and 18), Graves’ disease in the mother had not been recognized until transient CH-C was diagnosed.

Discussion

Transient CH-C occurs in infants born to mothers who develop hyperthyroidism during their pregnancy because of inadequately treated Graves’ disease [7-11]. As shown in Table 2, 5 cases of transient CH-C were identified by the measurement of low FT4 levels through newborn screening. To our knowledge, this is the first systematic audit of transient CH-C patients identified through FT4 screening.

As observed in our patients, FT4 levels in transient CH-C may be markedly low [7-11], and hypothyroidism in transient CH-C may persist for more than 1 year [8, 11]. In addition, the transition from CH-C to CH-T due to thyroid disintegration has been reported, similar to that noted in patient 14 in the present study [10]. Accordingly, failure to identify and treat this condition will likely result in serious intellectual disabilities [11]. Of the 5 patients with transient CH-C, 4 (patients 14, 16, 17, and 18 in Table 2) did not undergo thyroid function evaluation until the screening results had been reported. In other words, these 4 patients may have been overlooked if they had not undergone FT4 screening. It is of particular interest that in 3 patients (patients 14, 17, and 18), Graves’ disease in the mother had not been recognized until transient CH-C was diagnosed.
in the newborns. We are aware of 4 additional similar cases in the NMC-KPMA database, in which the newborns were born after the study period (unpublished data); this situation was also previously described in a US patient [9].

When maternal Graves’ disease is recognized prior to conception, pertinent treatment may be provided during pregnancy, and CH-C is not likely to develop in newborns. However, when maternal Graves’ disease develops during pregnancy, the features of hyperthyroidism may go unnoticed by obstetricians. The resulting untreated Graves’ disease increases the risk of transient CH-C in newborns, and even worse, this risk cannot be discernible by pediatricians and/or neonatologists.

Based on the above findings, we believe that this condition qualifies as a target entity of newborn screening, because the level of risk posed by transient CH-C is sufficiently high and screening by FT4 measurement can facilitate identification of patients for prompt treatment. In addition, through this screening, the real incidence of maternal Graves’ disease with onset during pregnancy may become evident.

CH-T with delayed TSH elevation has been described mainly in preterm newborns (especially in newborns with a gestational age of <37 weeks), LBW newborns, sick and preterm newborns admitted to the NICU, and newborns from multiple births [4, 12-16]. In these situations, the diagnosis of CH-T may be overlooked due to the suppression of the TSH level as a result of various drugs, hypothalamo-pituitary immaturity, and other effects of serious illness [17, 18].

Although thyroid dysfunction in these patients may be mild and/or transient, and long-term outcome data are scarce, according to a recent review, appropriate treatment should be considered in these patients [17]. In a series reported by Woo et al., 16% of patients with CH-T with delayed TSH elevation had a TSH level >50 µIU/mL [12]. This indicates that at least a small portion of these patients may have moderate to severe hypothyroidism.

Based on such findings, the need to detect this condition through newborn screening has been globally recognized. For this purpose, repetitive TSH level measurement is recommended for preterm and/or LBW newborns [14-16]. In Kanagawa Prefecture, an additional filter paper sampling is routinely requested for newborns with a birth weight of <2,000 g at approximately 1 month of age, and this sample is treated as the first sample.

As shown in Table 3, 6 cases of CH-T with delayed TSH elevation were detected by the measurement of low FT4 level with normal TSH level in the first

screening sample. Two of them (patient 20 and 23) were mature patients. According to the strict definition, they should not be included in the CH-T with delayed TSH elevation category, because this concept has been considered mainly in premature and/or LBW newborns and non-thyroidal illness cannot be excluded in these 2 patients. However, in the present study, we included these patients in this category because it is evident that they benefited from the FT4 screening. In addition, the presence of CH-T is probable in these patients, considering high TSH levels (30.4 µIU/mL and 35.2µIU/mL, respectively) at the confirmatory testing (Table 3).

Two mature newborns mentioned above (patient 20 and 23) and two other newborns (patient 19 and 21) may have been checked by TSH screening alone, if repetitive filter paper sampling in every sick newborn were mandatory. However, in reality, routine request for repetitive sampling for all sick newborns seems to be impractical, considering the higher screening cost and the increased burden of medical staff.

Remaining 2 were infants with a birth weight of <2,000 g from whom the first sample had been obtained at approximately 1 month of age, indicating that more than a month was required for their TSH level to recover from suppression. Thus, these results suggest that FT4 measurement allows for the detection of CH-T with delayed TSH elevation in newborns experiencing markedly slow TSH recovery, as well as in newborns with TSH suppression due to critical illness.

The identification of 24 true-positives over the study period yields a detection rate of 1 in 30,833 births, which is similar to the incidence of congenital adrenal hyperplasia (1 in 18,000 births) and exceeds that of phenylketonuria (1 in 114,379 births) in Japan [19, 20]. Screening for CH-C was formerly criticized as inefficient because of the rarity of CH-C, but it is now recognized that CH-C is more prevalent than previously thought [6, 21, 22]. Following the inclusion of transient CH-C and CH-T with delayed TSH elevation as the target entities for screening with FT4 measurement, this system may be considered to be more efficient than currently thought.

In conclusion, our study revealed that use of the FT4 screening system allows for the identification of a substantial number of cases of transient CH-C and CH-T with delayed TSH elevation. This is a clear advantage of the simultaneous measurement of FT4 and TSH. We insist that this strategy should be evaluated under the condition where these entities are included as targets of screening.
