Kuma Hospital, Center for Excellence in Thyroid Care, Kobe 650-0011, Japan

Abstract. Infertile women sometimes associated with subclinical hypothyroidism (SCH). The guidelines of the American Endocrine Society, and American Association of Clinical Endocrinologists and American Thyroid Association recommend treatment with thyroxine (T4) for patients with SCH who want to have children. We examined 69 female infertile patients with SCH and the effects of levothyroxine (l-T4) therapy on pregnancy rates and pregnancy outcomes were observed. Fifty-eight (84.1%) patients successfully conceived during the T4 treatment period (Group A), although 17 patients (29.3%) had miscarriage afterward. The remaining 11 patients continued to be infertile (Group B). The median TSH value in Group A before the T4 treatment was 5.46 μIU/mL (range 3.1-13.3) and this significantly decreased to 1.25 μIU/mL (range 0.02-3.75) during the treatment (<0.001). The estimated duration of infertility before the T4 treatment was 2.8±1.7 years and the duration until pregnancy after the treatment was significantly shorter at 0.9±0.9 years (<0.001). Shortening of the infertile period after the T4 therapy was observed not only in patients who were treated with assisted reproductive technology (ART) but also in patients who conceived spontaneously in Group A. Administered T4 dose was 54.3±14.2 µg before pregnancy and 68.5±22.8 µg during pregnancy (<0.001). Anti-thyroid autoantibodies were identified in 42.0% of all patients and no significant difference was observed in positivity between Group A and Group B. High success pregnancy rate and shorter duration of infertility until pregnancy after T4 treatment strongly suggest that T4 enhanced fertility in infertile patients with SCH.

Key words: Subclinical hypothyroidism, Infertility, Thyroxine therapy, Anti-thyroid antibodies, Pregnancy
hypocholesterolemia with TSH > 2.5 μIU/mL [13]. In this study, therefore, we examined the effects of T4 treatment on infertility in women with SCH.

**Materials and Methods**

**Patients**

We prospectively examined 69 infertile patients with SCH between January 2007 and December 2012. These patients were referred to our Kuma Hospital from the 16 infertility clinics because of high TSH found by screening tests. Infertility was diagnosed in patients who were fundamentally unable to conceive a baby for at least one year. Patients with male cause of infertility in their partners have been excluded. When high TSH more than 3.0 μIU/mL was reconfirmed in Kuma Hospital, treatment with 25 to 50 μg per day of T4 was started. When starting T4 treatment, 9 patients were under treatment with artificial insemination by husband (AIH) or ART and the rest 60 patients were not treated with these techniques yet. T4 dose was adjusted to keep TSH levels less than 3.0 μIU/mL before pregnancy and less than 2.5 μIU/mL during pregnancy. Finally patients were divided into two groups: successfully conceived, Group A and could not conceive, Group B. Patients were informed of the therapy and gave their consent to the study. The protocol was approved by the Ethical Committee of Kuma Hospital.

**Normal range of TSH in Japanese women of childbearing age and the definition of SCH**

Since TSH values are known to be influenced by age, ethnic differences, and measuring assay kits, we attempted to establish the normal range of TSH in Japanese women of childbearing age using 131 normal women aged between 15 and 45 years old (mean 34). Subjects taking excess iodine and with positive TgAb and/or TPOAb or an abnormal thyroid, as confirmed by ultrasonography were excluded. The 95% confidence interval was found to be 0.39 to 3.04 μIU/mL. Therefore, the diagnosis of SCH was made by normal Free T4 (FT4) and TSH levels of more than 3.0 μIU/mL.

**Thyroid function and autoantibodies**

TSH, FT4, and Free T3 (FT3) concentrations were measured using chemiluminescent immunoassays (Architect TSH, Architect FT4, and Architect FT3, respectively; Abbott Japan Co., Tokyo, Japan). Normal ranges were 0.4–3.0 μIU/mL for TSH, 0.7–1.4 ng/dL for FT4, and 1.8–3.5 pg/mL for FT3. Inter-assay CVs of measurements for normal TSH levels were 2.0–3.0%. Serum levels of the thyroglobulin antibody (TgAb) and anti-thyroid peroxidase antibody (TPOAb) were measured using an electrochemiluminescence immunoassay (ECLusys 2010; Roche Diagnostics Japan Co., Tokyo, Japan; normal range: < 39.9 IU/mL for TgAb, and < 27.9 IU/mL for TPOAb).

**Statistical analysis**

Comparisons of TSH values and the estimated durations of infertility before and after the T4 treatment were performed by the paired T test for paired samples. A comparison of T4 administered before and during pregnancy was also calculated by the paired T test. Differences in age, prevalence of antibodies, and infertility treatment were analyzed between Group A and Group B by the Mann-Whitney test, Fisher exact test or chi square test. Differences were considered to be significant at $p < 0.05$.

**Results**

Fifty-eight of 69 (84.1%) infertile women with SCH successfully conceived after the T4 treatment (Group A). The remaining 11 patients continued to be infertile (Group B) for observation period of 3.3±2.2 years (0.6~6 years) (Table 1). No significant difference was observed in the age and prevalence or activities of TgAb and/or TgAb between the two groups. Regarding the infertility treatment method, 25 patients were observed spontaneously or with timed intercourse, 9 with AIH, 33 with in vitro fertilization-embryo transfer (IVF-ET), and 2 with intracytoplasmic sperm injection (ICSI) (Table 1). The treatment proportions of none (including timed intercourse), AIH or ART (IVF-ET and ICSI) were similar between two groups (Table 1). The median TSH and mean FT4 values before the T4 treatment (data at first visit) were also similar between two groups. The median TSH values in Group A before the T4 treatment was 5.46 (range 3.1–13.3) μIU/mL and significantly decreased to 1.25 (range 0.02–3.75) μIU/mL ($p < 0.001$) after the treatment for 2–4 months (Table 1). In Group B similar changes in TSH were observed, before 5.10 (range 3.1–17.4) μIU/mL and after 1.90 (range 0.07–4.43) μIU/mL. The FT4 values in Group A before the T4 treatment was 0.98±0.13 ng/dL and significantly increased to 1.23±0.22 ng/dL ($p < 0.001$) after the treatment. The FT3 values before the T4 treatment was 2.75±0.32 pg/
Hypothyroidism and infertility

A moderate dose of T4 was needed before pregnancy (54.3±14.2 µg per day) and a larger dose (68.5±21.8 µg per day) were necessary to keep TSH less than 2.5 μIU/mL during pregnancy in Group A. Twelve patients (20.7%) in group A conceived within 3 months and 14 (24.1%) conceived within 6 months. Finally, 44 patients (75.8%) had conceived within one year after the T4 treatment.

In order to remove the possible effects of AIH or ART technologies, we analyzed patients who conceived spontaneously before and after T4 treatment (including timed intercourse). As shown in Table 1, high TSH levels and did not change after the treatment (2.78±0.46 pg/mL). In Group B similar changes in FT4 were observed (Table 1).

The estimated duration of infertility in Group A was compared between before and after the T4 treatment until pregnancy in both groups of no infertility treatment and AIH+ART treatment (Table 2). The infertile period was similarly shorter after the T4 treatment in both groups (p < 0.001). In all 58 patients, 2.8±1.7 years reduced to 0.9±0.9 years (p < 0.001) after T4 treatment. Used dose of T4 was higher during pregnancy than that of before pregnancy in both groups (p < 0.001) (Table 2). A moderate dose of T4 was needed before pregnancy (54.3±14.2 µg per day) and a larger dose (68.5±21.8 µg per day) were necessary to keep TSH less than 2.5 µU/mL during pregnancy in Group A. Twelve patients (20.7%) in group A conceived within 3 months and 14 (24.1%) conceived within 6 months. Finally, 44 patients (75.8%) had conceived within one year after the T4 treatment.

In order to remove the possible effects of AIH or ART technologies, we analyzed patients who conceived spontaneously before and after T4 treatment (including timed intercourse). As shown in Fig. 1, high TSH levels

(median 6.14, range 3.3-12.7 μIU/mL) decreased significantly (median 1.57, range 0.01-4.0 μIU/mL) ($p < 0.001$) by the T4 treatment. The estimated infertile period before the T4 treatment (2.1±1.4 years) was also significantly shortened (0.87±1.1 years) ($p < 0.001$) (Table 2). We examined non-thyroidal infertility factors, such as endometriosis, other uterine problems, ovarian and tubal factors, anti-phospholipid antibodies and anti-nuclear antibodies. These factors were found in 32.8% and 45.6% in Group A and Group B, respectively, but difference was not significant between the two.

A high pregnancy rate was observed after T4 treatment in the present study; however, 17 cases (29.3%) had a miscarriage. We analyzed various factors between the subgroup of live birth or continued pregnancy more than 24 gestational weeks (non-miscarriage subgroup) and miscarriage subgroup (Table 3). Mean age at pregnancy in miscarriage subgroup was 37.5±3.1 and significantly higher than that of non-miscarriage subgroup (34.9±4.1, $p < 0.05$). AIH or ART therapy were conducted in 82.3% of patients in miscarriage subgroup and was 53.6% in non-miscarriage subgroup, and difference between the two was significant ($p < 0.05$). Anti-thyroid autoantibodies were similarly found in 39% and 41% in non-miscarriage and miscarriage subgroups, respectively. Non-thyroidal miscarriage factors, such as endometriosis, other uterine problems, anti-phospholipid antibodies and anti-nuclear antibodies, were found in 24.4% and 35.3% in non-miscarriage and miscarriage subgroups, respectively, but difference between the two was not significant.

### Discussion

We found 84.1% of infertile women with SCH successfully conceived after the T4 treatment. Moreover, 75.8% of them had conceived within one year after initiation of treatment. SCH has various causes and 60–80% of cases are associated with autoimmune thyroiditis [3]. On the other hand, anti-thyroid antibodies were found in 1.9–30.5% of infertile patients [4]. It is well described that positive anti-thyroid antibodies are associated with high frequency of miscarriage [2, 15-17] but thyroid autoimmunity per se does not alter the implantation of embryo[17, 18]. In this study, anti-thyroid antibodies were found in 42.0% of patients but no significant differences were observed between Group A and Group B, suggesting that presence of anti-thyroid antibodies may not be a key factor of fertility.

In 1999, Lincoln et al. [19] reported that thyroxine treatments for hypothyroidism in infertile women with ovulatory dysfunction resulted in successful pregnancies in 64% of patients. None of these women had the overt clinical signs or symptoms of hypothyroidism, which suggested that the T4 treatment for probable SCH enhanced fertility. Abalovich et al. [9] examined 34 SCH women with infertility. They reported a pregnancy rate of 44.1% with a T4 treatment; however, the precise dose of T4, duration of infertility, and other information including the ART treatment were not described. Verma et al. [10] more recently reported that 76.6% of infertile patients with hypothyroidism, both the clinical and subclinical forms, conceived within one year of receiving a T4 treatment. However, the effectiveness of T4 only in patients with SCH remains unknown and no information is available on the ART treatment. The clinical pregnancy rate was shown to be significantly higher in T4-treated infertile patients with SCH undergoing in vitro fertilization than in those not receiving the T4 treatment [11, 20], although effect of T4 therapy was doubtful in other reports [2, 12, 13]. In our study, 84.1% of infertile patients with SCH

*Significantly higher age than that of live birth or pregnancy more than 24 weeks at $p < 0.05$

** Significantly different from value of before T4 treatment at $p < 0.001$

AIH, artificial insemination by husband; IVF-ET, in vitro fertilization-embryo transfer; ICSI, intracytoplasmic sperm injection
conceived after the T4 treatment, strongly suggesting that T4 treatments for infertile women with SCH may induce a favorable effect on fertility.

Recent progress in ART technique may increase the fertility rate. However, high pregnancy rate (84.0%, 21/25) obtained in patients without AIH or ART therapy (Table 1), strongly suggests that the T4 treatment itself was useful for enhancing fertility. The shorter infertility period observed after the T4 treatment without ART therapy in Group A further supports the effectiveness of the T4 treatment. We compared non-thyroidal infertile factors between Group A and Group B, but could not find significant difference between the two.

A high pregnancy rate induced by the T4 treatment is a desirable result for infertile women with SCH but problem is a high miscarriage rate. It is well established that anti-thyroid autoantibodies are significantly associated with higher miscarriage rate [2, 15-17]. However, positivity was similar between non-miscarriage and miscarriage subgroups. Verga et al. [21] reported the importance of L-T4 substitutive therapy in pregnant women with SCH, especially in the first trimester of pregnancy. However we could not find differences in TSH values before miscarriage between non-miscarriage and miscarriage subgroups. Mean age at pregnancy was high and frequency of AIH or ART therapy was also high in miscarriage subgroup, suggesting that age and infertility therapy were significantly related to the miscarriage. It is important to elucidate more precisely the mechanisms of these abortions.

The mechanism for the T4-induced enhancement in fertility has not yet been elucidated in detail. Possibly SCH influence the hypothalamus-pituitary-gonadal axis and may cause menstrual abnormalities, anovulation, hyperprolactinaemia and so on [4, 22] and T4 therapy may improve these conditions [14, 23]. Cramer et al. reported that TSH may predict for fertilization in IVF and reflect the importance of thyroid hormones in oocyte physiology [24]. Kim et al. reported that T4 treatment may stimulate directly oocyte and improve embryo quality in their successful study of in vitro fertilization / intracytoplasmic sperm injection in infertile SCH women [20].

Finally, randomized controlled trials involving infertile patients with SCH need to be conducted in order to confirm the effectiveness of the T4 treatment. This may ultimately provide reliable evidence to make clinical decisions in the treatment of SCH patients with T4.

In conclusion, the T4 treatment for infertile patients with SCH may be useful for enhancing fertility.
