Synopsis

Urinary kallikrein in a patient with Bartter's syndrome was remarkably higher than normal. Indomethacin treatments increased serum potassium concentration and urinary Na/K ratio, and improved the response of blood pressure to angiotensin II infusion, while it decreased plasma renin activity, plasma aldosterone and urinary kallikrein.

The purified urinary kallikrein had one component of the iso-electric point 4.3 by isoelectric focusing using Ampholine system, and its molecular weight was $4.2 \times 10^4$, which was greater than those of three components of normal human urinary kallikreins (normal HUK). Also Km values with TAME and BAME of urinary kallikrein in our patient with Bartter's syndrome did not correspond to those of normal HUK. Thus it can be said that urinary kallikrein in our patient with Bartter's syndrome was qualitatively different from normal HUK. The present observation might be a reflection of renal tubular dysfunction in this patient with Bartter's syndrome.

Bartter's syndrome is characterized by hyperreninemia, excessive aldosterone production, hypokalemia, metabolic alkalosis, J.G. cell hyperplasia, vascular-insensitivity to angiotensin II and an abnormality in the renal tubular reabsorption of sodium (Solomon and Brown, 1975; Tomko et al., 1976). Recent studies demonstrated the excessive production of prostaglandin and kallikrein in Bartter's syndrome, both of which are vasodepressive and natriuretic substances and could be closely related to the underlying pathogenesis of this syndrome (Gill et al., 1976a; McGiff, 1977). Here we have investigated the character of urinary kallikrein in one patient with Bartter's syndrome and found its properties were somewhat different from those of normal subjects.

Case Report

A 48-year-old woman was admitted to hospital with a history of progressive muscular weakness, polydypsia and polyuria.
About 2 months prior to admission, she developed progressive fatigability, muscular weakness and occasional attacks of nausea and vomiting. A marked hypokalemia was found and the patient was referred to our hospital for the evaluation of hypokalemia. Ten years ago, hypokalemia was noted and she received potassium supplements for a short period. Since then polydypsia and polyuria have been noted. She denied any medication inducing hypokalemia. Her family history was non-contributory. On admission, she appeared to be emaciated, slightly dehydrated and could not walk without assistance. She had a height of 155 cm and a weight of 30 kg. The blood pressure was 98/58 mmHg and the pulse rate 86/min and regular. The examinations of chest, heart and abdomen were normal. Neurological examination showed generalized muscular weakness. On the first hospital day, plasma sodium was 131 mEq/l and plasma potassium was 1.9 mEq/l. Creatinine clearance was 50–58 ml/min. Plasma calcium and phosphorus concentrations were normal. Liver and pancreatic functions were normal. Glucose tolerance test was normal. Glucose tolerance test was normal. On a regular hospital diet (sodium 200–250 mEq/day) with potassium supplement (potassium 180 mEq), the patient excreted 3–6 liters urine containing about 320–410 mEq sodium and 175–260 mEq potassium. The urine specific gravity was 1.006–1.008.

Urinalysis was negative for protein or sugar and urine pH ranged from 6.0 to 9.0. Urine culture was negative. Ammonium chloride acidification test showed a decrease in urine below pH 6.0. Thyroid function, 17OHCs and 17KS were normal. Intravenous pyelogram demonstrated a somewhat delayed appearance of dye in both kidneys and slight bilateral dilation of the collecting system. Renal biopsy showed a marked hyperplasia of the juxtaglomerular apparatus.

**Materials and Methods**

Sephadex G-75, G-100 and QAE-Sephadex A-50 (3.0104 mEq/g) were obtained from Pharmacia Fine Chemicals, Uppsala, Sweden. DEAE-cellulose (0.92 mEq/g) were purchased from Brown Chemicals, U.S.A. Carrier Amphorite (pH range 3.5 to 5.0) was purchased from LKB Produkter AB, Sweden. AcAME, AGlME, AME, BAME, LME, TAME and TLME were supplied from Peptide Institute Co., Ltd., Osaka, Japan. PAME and ZAME were kindly supplied from Dr. Kouichi Dobashi, Teikoku Hormone Mfg. Co. Ltd. Angiotensin II (Hypertensin Ciba) was a gift from Chiba Geigy Co. Ltd., Tokyo.

Plasma renin activity and plasma aldosterone concentration were measured by radioimmunoassay (CEA-IRE-SORIN, France).

**Esterolytic activity**

Esterolytic activities of HUK were measured by the three methods, e.g., fluorometry (Matsuda et al., 1976a), colorimetry (Moriwaki et al., 1971) and spectrophotometry (Schwert & Takenaka, 1955; Hummel, 1959), using BAME, TAME and other synthetic substances as substrates. All of these three methods were in good agreement. All of esterolytic activities were expressed in terms of esterase unit (E.U.) which is identical in terms of µ moles substrate hydrolyzed per min.

**Vasodilator activity**

This was assayed by the method reported previously (Moriya et al., 1965), by measuring the increase in arterial blood flow in dogs. This activity was expressed in terms of kallikrein units (K.U.).

**Purification of urinary kallikrein**

Purification was carried out under the methods and experimental conditions as previously reported (Matsuda et al., 1976b) with a slight modification. Briefly, deionized water was added to the original urine (12.7l), made up to 120l. After adjusting the pH 7.0 to 7.5, 40 g of DEAE-cellulose was added to the solution. After absorption by stirring for 2 hr and then DEAE-cellulose was packed in a column (3.6 x 50 cm). Crude extracts were eluted with 0.05 M phosphate buffer, pH 7.5 containing 0.5 M NaCl. This crude extract was purified by the following procedures, e.g., DEAE-cellulose chromatography, Sephadex G-100 gel filtration, QAE-sephadex A-50 chromatography and Sephadex G-75 gel filtration in this order. Final preparation of urinary kallikrein was used for the investigations.

**Isoelectric focusing fractionation**

Isoelectric focusing fractionation was performed.
as reported previously (Matsuda et al., 1976b). Briefly isoelectric focusing was performed with carrier ampholyte (pH 3-5) on LKB8100 equipment. Electrophoresis was carried out at 500 volts and 6-8°C for 40 hr.

**Determination of protein concentration**

Protein concentration was determined spectrophotometrically by measuring the absorbance at 280 nm, using a Hitachi spectrophotometer, model 124 with a cell of 1 cm light path, and the amount of protein was calculated taking a value for the extinction coefficient of HUK, E_{280}^{	ext{mg}} of 14.1.

**Results**

**Hospital course (Fig. 1)**

When the patient was put on a regular hospital diet (sodium 200–250 mEq/day) with potassium gluconate (180 mEq potassium), there was noted a gradual return of serum potassium up to 2.8–3.2 mEq/l from 1.9 mEq/l. Then her muscle strength returned and she was able to be up and about. Subsequently potassium supplements were discontinued. Serum potassium again fell to 1.6 mEq/l. At this time urinary kallikrein ranged from 27.3 to 50.1 E.U./day (normal range 8.60 ± 3.8 E.U./day) and plasma renin activity 26.04–45.47 ng/ml/hr (normal range 1.68 ± 1.18) and plasma aldosterone 2282.5–2839.7 pg/ml (normal range 147.1 ± 81.6 pg/ml). Then 75 mg of indomethacin was administered. There was noted an increase in serum potassium to 2.8–3.2 mEq/l, which was accompanied by a decrease in plasma renin activity to 4.6–8.2 ng/ml/hr, plasma aldosterone to 380.5–420.7 pg/ml and urinary kallikrein to 12.6–14.5 E.U./day. Since then she has been treated with 75 mg of indomethacin and 180 mEq of potassium gluconate. Serum potassium gluconate. Serum potassium has ranged between 3.2–3.8 mEq/l and the patient gained weight by about 11 kg during her hospitalization.

**Angiotensin II infusion test (Fig. 2)**

The pressor response to angiotensin II was measured at a rate of infusion of 10 ng/kg/min of angiotensin II for 60 min, when the patient was receiving potassium supplements alone and also indomethacin together with potassium supplements. Without indomethacin, there was virtually no

Fig. 1. Effect of 75 mg/day of indomethacin administration on urinary kallikrein, urinary Na/K ratio, serum K, plasma renin activity and plasma aldosterone.
Estimation of the molecular weight (Fig. 3)

The molecular weight of the components of normal HUK and urinary kallikrein in the patient with Bartter's syndrome was estimated by gel filtration on a Sephadex G-100 column. The approximate molecular weight of urinary kallikrein in the patient with Bartter's syndrome was $4.2 \times 10^4$, which was greater than those of normal HUK (HUK-1 and HUK-2 $2.7 \times 10^4$, and HUK-3 $2.9 \times 10^4$) as reported previously by Matsuda et al. (1976 b).
Estimation of Km values (Table 2)

Km values towards synthetic N-substituted arginine esters (TAME and BAME) were determined. As demonstrated in Table 2, Km values of the purified urinary kallikrein in our patient with Bartter's syndrome was not correspondent with any one of those three components of normal HUK.

Isoelectric focusing fractionation (Fig. 4)

The purified urinary kallikrein in our patient with Bartter's syndrome was applied to an Ampholine column. As shown on the left side, one component of urinary kallikrein was obtained in our patient, of which the isoelectric point was pI 4.3. On the contrary, as shown on the right side, three components of urinary kallikrein purified from the urine collected on a large scale from normal male persons were separated by isoelectric focusing and were named HUK-1 (Human Urinary Kallikrein 1, pI 3.9), HUK-2 (pI 4.0) and HUK-3 (pI 4.2), respectively.

Esterolytic activities of the purified urinary kallikreins towards N-substituted arginine and lysine esters (Table 3)

Esterolytic activities of the purified urinary kallikreins obtained from normal subjects and the patients with Bartter's syndrome towards various synthetic arginine and lysine esters were investigated. As demonstrated in Table 3, esterolytic activities of urinary kallikreins in our patients with Bartter's syndrome showed only a slight difference, compared with those of any one of these three types of normal HUK.

Km values of urinary kallikreins from normal subjects (Matsuda et al., 1976) and the patient with Bartter's syndrome towards TAME and BAME were determined by Lineweaver-Burk plots. Esterolytic activities were assayed spectrophotometrically, measuring the increase in absorbancy at 247 nm (TAME) and 254 nm (BAME).

*: Trace.

Spectrophotometrically measured esterolytic activities of three components of normal HUK, mixed normal HUK and urinary kallikrein of Bartter's syndrome using various N-substituted synthetic arginine and lysine esters were compared with esterolytic activity of these kallikreins using TAME as substrate.

Discussion

Exceedingly high values of urinary kallikrein and the restoration of pressor response to angiotensin II after the administration of indomethacin in our patient with Bartter's syndrome are in agreement with the previous reports (Lechi et al., 1976; Halushka et al., 1977). Indomethacin, an inhibitor of prostaglandin synthesis, suppressed the renin-angiotensin-aldosterone system, decreased urinary kallikrein in this patient and increased serum potassium concentration. But they were not corrected to normal levels, similar to the report by Gill et al. (1976a). Urinary kallikrein has been reported to be also high in primary aldosteronism in which the renin-angiotensin system is suppressed by the excess of aldosterone production (Margolius et al., 1974).

So in Bartter's syndrome and primary aldosteronism, the stimulation and the suppression of the renin-angiotensin system, though opposite in direction, are associated with an increase in urinary kallikrein excretion and aldosterone production. Moreover, spironolactone, aldosterone anagonist is said to decrease kallikrein excretion (Lechi et al., 1976; Margolius et al., 1974). Thus the evidence described above favours the hypothesis that kallikrein excretion is primarily related to mineralocorticoids such as aldosterone. Then the explanation for the decline of urinary kallikrein excretion by indomethacin therapy in our patient is that indomethacin inhibited a prostaglandin mechanism which participated in the regulation of renin-angiotensin system, leading to an decrease in aldosterone production followed by a decline of urinary kallikrein excretion, though there still remain another possibility that the decreased renal prostanglandins with indomethacin administration alter the activity of the kallikrein-kinin system (Halushka et al., 1977).

From the data presented here, it can be mentioned that isoelectric point, molecular weight and Km value in our patient did not correspond to those observed in any one of the three types of urinary kallikrein reported previously by Moriya et al., suggesting that the character of urinary kallikrein of this patient did qualitatively differ from normals. According to Moriya and his co-workers, the molecular weight of dog renal kallikrein was larger than that of dog urinary kallikrein (Moriwaki et al., 1976). A similar finding was also found in rat (Porcelli et al., 1975). They suggested that the urinary kallikrein might be a partial degradation of renal kallikrein.
Then it may be speculated that the urinary kallikrein in our patient with Bartter's syndrome was renal kallikrein which was not degraded.

A renal tubular defect has been reported to be at least in part responsible for the pathophysiology of Bartter's syndrome (Tomko et al., 1976; Gill et al., 1977b). As urinary kallikrein is said to be of renal origin (Nustad et al., 1975), so the present findings might be a reflection of renal tubular dysfunction in this patient. Nevertheless, it is notable that urinary kallikrein in our patient was still under the influence of renin-angiotensin-aldosterone system or renal prostaglandins system.

Whether this derangement is a primary or secondary phenomenon in Bartter's syndrome is still indeterminate.
