Abstract

A simplified method for the determination of natriuretic factor in the urine as measured by digoxin-like substance was studied. Digoxin-like substance in the urine was estimated by RIA using anti-digoxin antibody after being extracted by reversed phase cartridge column but without gel filtration. The values found by radioimmunossay (RIA) yielded a significant correlation with those of the inhibitory effect of Na-K-ATPase activity which was measured by biochemical assay as described by Hamlyn et al.

Using this RIA method, the effect of salt intake on natriuretic factor in urine was studied in patients with essential hypertention. The natriuretic factor on a high sodium diet (NaCl 20g/day for three days) increased approximately 1.5 times, as compared to those on a low sodium diet (NaCl 3g/day) (p<0.05). The Natriuretic factor showed a positive correlation with urinary Na excretion (P<0.050) when the patients were placed on ad. lib. sodium diet. From these results, it is suggested that secretion of natriuretic factor in the urine might be regulated in part by salt intake.

In a cross-circulation experiment, de Wardener et al., 1961 first observed that the extracellular fluid (ECF) volume expansion causes marked natriuresis which may be produced by a hormone-like substance in the circulating blood. Since then biological and immunological properties of this hormone-like substance such as an inhibitory effect on activity of Na-K-ATPase (Gonic et al., 1977) and cross-reactivity with digoxin antibody (Gruber et al., 1980) have been disclosed. Various methods have been developed and are used for the determination of this substance. However, these methods included troublesome purification procedures and this hampers clinical application. In the present study, we have established a simple and rapid method for the determination of natriuretic factor in human urine, using its immunological property to cross react with anti-digoxin antibody. We also studied the effect of salt balance on the natriuretic factor in human urine.

Material and Methods

Methods

200 ml of urine was adsorbed in a reversed phase cartridge column (SEP-PAK C 18, Waters Co., Ltd., USA) washed with 0.1% TFA 20 ml and petroleum ether 10 ml and eluted with acetonitrile: 0.1% TFA (80:20) 5.0 ml. The elute was lyophilized (sample A), and filtered with Sephadex G-25 (Pharmacia Fine Chemicals, Superfine, diameter; 0.9 cm, length; 70 cm, solvent; 0.1% TFA, Flow rate; 1.2 ml/min, fractionation for 5 minutes). Digoxin-like substance in each fraction was determined by RIA. Commercial kits made available by Daiichi Radioisotope Co., Ltd. were used for RIA. RIA yielded a single peak of digoxin-like immunoreactivity after salt fraction (Fig. 1 lower column).

To compare with conventional methods, a 200 ml of urine was lyophilized (sample B) and separated by gel filtration with Sephadex G-25 similarly to sample A. The Gel filtration pattern of sample B showed a single peak of the same site as that of sample A (Fig. 1). Moreover, on comparing treated sample A separating to post-salt fraction by gel filtration (F2 in Fig. 2) and untreated sample A, there was found to be no difference in values by RIA. Namely, as the substance interfering with RIA is removed by extraction with a reversed phase cartridge column, gel filtration might be unnecessary to determine the natriuretic factor as digoxin-like substance by RIA. Thus, for subsequent determinations, only extraction with reversed phase cartridge column but gel filtration was carried out.

Secondly, for the quantitative determination of natriuretic substance, the correlation between the values obtained by RIA using antidigoxin

![Fig. 1. Gel filtration profiles on Sephadex G-25.](image-url)
antibody and the inhibitory effect on Na-K-ATPase activity was studied. The inhibitory effect on Na-K-ATPase activity was determined according to Hamlyn et al.'s method (Hamlyn et al., 1982). In brief, the decreasing ratio was determined as the change in absorbance at 340 nm by utilizing the change from NADH to NAD coupling the change of ATP to ADP. To assay cocktail (KCl 20 mM, NaCl 100 mM, MgSO4 4.5 mM, EGTA 5 mM, Na2ATP 3 U, PEP 1.2 mM, NADH 0.25 mM, TES-tris 40 mM, pH 7.4, LDH 1.2 U and PK 1.2 U in 1.0 ml., these reagents were obtained from SIGMA Chemical Company or Oriental Yeast Co., Ltd.) 780 µl, distilled water 200 µl (control), or sample 200 µl was added to make 980 µl. Then, to this solution, canine kidney Na-K-ATPase suspension 20 µl (SIGMA Chemical Company, 3 µg protein) was added and reaction was started at 37°C. The change in absorbance at 340 nm was recorded with the time course. Percentage inhibition was calculated by means of the following formula.

\[
100 - \frac{\text{A}_{340 \text{ min}} \text{sample}}{\text{A}_{340 \text{ min}} \text{control}} \times 100.
\]

Calculation of inhibition ratio on Na-Ka-ATPase and RIA using anti-digoxin antibody was carried out in each sample, which was extracted from the urine 200 ml using a reversed phase cartridge column, and the values obtained by these 2 methods were compared. These methods showed a significant positive correlation (r=0.855, p<0.01), which passes the original point (Fig. 2). Thus, it was suggested that natriuretic factor in the urine may be evaluated quantitatively RIA using anti-digoxin antibody.

**Materials**

Nineteen hospitalized patients with mild or moderate (WHO I–II stage) essential hypertension were studied after informed consent was obtained. They were given low salt diet (NaCl 3 g/day) for three days and a high salt diet (NaCl 20 g/day) for the subsequent 3 days after ad. lib. diet for about 2 weeks. On the third day of each diet, 24 hour urine was collected and digoxin-like substance and aldosterone in the urine were determined. On the same day, after an overnight fast, the blood was withdrawn and used for the determination of PRA, Plasma aldosterone (p-aldo), serum Na and K. Urinary aldosterone after hy-

Mean±SE. *: p<0.05, **: p<0.01 VS NaCl restricted state

Following the increase in salt intake from 3 g/day to 20 g/day, the mean blood pressure rose slightly, PRA, PA and urinary aldosterone decreased significantly and the urinary excretion of Na increased significantly (Table 1).

Digoxin-like substance (DLS) in the urine increased from 19.0±3.0 ng/day on low salt diet to 31.9±3.7 ng/day on high salt diet (p<0.05, Fig. 3).

Furthermore, the relationship between urinary excretion of digoxin-like substance and sodium, aldosterone and age was studied in the duration of salt intake ad. lib. DLS in the urine showed significantly positive correlation with urinary excretion of sodium (r=0.5886, p<0.01) and there was a significantly negative correlation with urinary excretion of aldosterone (r=-0.4653, p<0.05, Fig. 4).

In the present study on a hypertensive patient without apparent nephropathy, we did not observe an age-related change in DLS (per day and per g creatinine, Fig. 5).

Results

Following the increase in salt intake from 3 g/day to 20 g/day, the mean blood pressure rose slightly, PRA, PA and urinary aldosterone decreased significantly and the urinary excretion of Na increased significantly (Table 1).

Discussion

A bioassay method (Clarkson et al., 1976) using rats, a method using inhibitory effect on Na-K-ATPase activity (Gonic et al., 1977) and RIA using an anti-digoxin antibody (Klingmuller et al., 1982) have been used conventionally for the determination of natriuretic factor. However, in the case of measuring it in urine, these methods employ lyophilization of massive urine and if necessary, many purification steps such as gel filtration, desalination, strict adjustment of pH and ion concentration in the solution. The present method using reversed phase cartridge column we have developed is a
simple procedure which enables condensation, desalination, deproteinzation to be done at one time and removes substances that may possibly interfere with RIA. Although RIA is a convenient method, it is not known whether it is consistent with other methods or not. Although it has been reported that the bioassay method gives results consistent with its inhibitory effect on Na-K-ATPase (Gonic et al., 1977, Hillyard et al., 1976) no correlation between RIA and the inhibitory effect on Na-K-ATPase activity has been demonstrated. As shown in Fig. 2, there was a significant positive correlation between the RIA and the methods using Na-K-ATPase. This suggests that the natriuretic factor in the urine can be estimated quantitatively by RIA using anti-digoxin antibody.

Expanded ECF is thought to be a major factor which regulates the natriuretic factor. Bioassay showed an increase in the natriuretic factor in the blood from dogs and
rats treated with blood transfusion (Hamlyn et al., 1982, Knock et al., 1980), or in the urine of humans (Clarkson et al., 1976, Klingmuller et al., 1982) who were given a high salt diet (Na; 300 mEq/day). In our study, a diet with 20 g/day of salt for 3 days produced a 1.5-fold increase in DLS in the urine compared to the period with 3 g/day of salt. de Wardener et al. (1981) demonstrated a 25 time increase in human subjects when a high salt diet was given. This difference may be due to (Clarkson et al., 1976) a difference in assay methods or (Clarkson et al., 1970) a difference in the salt loading period i.e. 3 days in our study and 5 days in de Wardner's study. Although we did not compare our RIA method with de Wardener's cytochemical technique for the determination of Na-K-ATPase activity, the possibility of the different assay methods cannot be neglected in view of our finding that the inhibitory effect on Na-K-ATPase using the conversion of NADH to NAD showed a significant correlation with the

![Fig. 5. Correlation between digoxin-like substance and age.](image-url)
RIA method but the slope of its regression line is as sharp as 16.4 (Fig. 2). Concerning the duration of the salt load, this study lasted only 3 days, but there is a tendency for DLS in the urine to increase more from 3rd day in preliminary examination with small cases, and the difference between de Wardener’s results and ours may be also possibly due to the fact that in the duration of the salt load was different.

Digoxin-like substance showed a positive correlation with urinary Na excretion and may indicate that Na balance plays an important role in the regulation of this substance. In addition, it showed a negative correlation with urinary aldosterone, but it is not known whether aldosterone per se effects DLS excretion or not.
