Abstract. We report the case of a 70-year-old man who developed hypothyroidism associated with TSH receptor antibodies and severe ophthalmopathy during lithium therapy. He had received lithium therapy for more than 20 years for manic depression, when ophthalmopathy (class VI of the American Thyroid Association classification) and mild hypothyroidism developed. Orbital magnetic resonance imaging indicated marked enlargement of the superior, medial and inferior rectus muscles in the left eye. He had anti-eye muscle antibodies in his serum, detected by Western blotting and quantified by chromatoscanning, as well as anti-TSH receptor antibodies. He was treated with supplementation of levothyroxine and four cycles of methylprednisolone pulse therapy. After the pulse therapy, both anti-eye muscle antibodies and anti-TSH receptor antibodies decreased and disappeared in parallel with the improvement in eye symptoms and signs. These observations suggest the importance of anti-eye muscle antibodies as clinical markers in the development of thyroid-associated ophthalmopathy.

Key words: Graves' disease, Ophthalmopathy, Lithium, Thyrotrophin receptor antibody, Eye muscle antibody. (Endocrinol Japon 39: 593-600, 1992)

THERE is now considerable evidence that thyroid-associated ophthalmopathy (TAO) is an autoimmune disorder [1]. TAO occurs in approximately 85% of patients with Graves' hyperthyroidism, and occasionally in association with Hashimoto's thyroiditis. To our knowledge, most patients with TAO have detectable serum anti-TSH receptor antibodies, even if they are associated with hypothyroidism [2], although a possible role of anti-TSH receptor antibodies in the development of ophthalmopathy has never been shown. Eye muscle antibodies as measured in enzyme linked immunosorbent assay [3, 4], antibody-dependent cell-mediated cytotoxicity assay [5] and Western blotting [6-9], have been found in sera from patients with TAO, although their precise roles in the development of TAO are still unclear.

In the present studies, we report a case of so-called "hypothyroid Graves' disease" [10] during lithium therapy. He developed ophthalmopathy and hypothyroidism without a history of hyperthyroidism. He had anti-eye muscle antibodies as well as anti-TSH receptor antibodies before methylprednisolone pulse therapy. After pulse therapy both antibody activities decreased and disappeared, as the symptoms and signs of...
ophthalmopathy improved, suggesting that anti-eye muscle antibodies may be useful clinical markers in the development of TAO.

Materials and Methods

Serum free triiodothyronine (T3), free thyroxine (T4) and thyrotropin (TSH) were measured with commercially available kits (Amerlite Free T3, Amerlite Free T4, Amersham, Tokyo, Japan and Delfia TSH, Pharmacia LKB Biotechnology, Tokyo, Japan, respectively). Anti-thyroglobulin antibodies were measured by a hemagglutination technique with commercial kits (Serodia ATG and Serodia AMC, Fujirebio, Tokyo, Japan). Anti-thyroglobulin antibodies were measured by a hemagglutination technique with commercial kits (Serodia ATG and Serodia AMC, Fujirebio, Tokyo, Japan). Anti-thyroid stimulating hormone antibodies were measured by a radioreceptor assay (Baxter, Tokyo, Japan). Thyroid stimulating antibody (TSAB) was measured as the % increase in cyclic AMP production by FRTL-5 cells [11] and thyroid simulation blocking antibody (TSBAB) was expressed as the % inhibition of TSH-induced cyclic AMP increase by FRTL-5 cells [12]. Anti-eye muscle antibodies were measured by Western blot analysis. Briefly, sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) of 100,000g membrane fractions of rat eye muscle was carried out under denatured conditions by the method of Laemmli [13] at 35 mA for 1 h and 70 mA for 3 h. Electrotransfer of rat eye muscle membrane proteins onto nitrocellulose paper was performed as described by Towbin et al. [14], with a trans blot cell (Bio-Rad) at 30 volts for 30 min and 60 volts for 3 h. Then the strips were washed and incubated for 30 min with 1:25 diluted sera, which were preabsorbed with rat liver acetone powder (SIGMA Chemical Co., St. Louis, Mo., USA) for 1 h. Positive reactivity was developed with commercial kits (Vectastain ABC-GO and a Substrate kit I for glucose oxidase, Vector Laboratories Inc., Burlingame, CA., USA). To quantify the binding activity of the bands, each strip was chromato-scanned with a Shimadzu CS-950 (Shi-

madzu Inc., Kyoto, Japan) [15]. Anti-eye muscle antibody activity was expressed as the ratio of intensity of the positive band at 64 kDa/that of control band which was seen at 66 kDa in all strips as putative endogenous avidin-binding activity. 25 normal subjects, 9 men and 16 women, aged 22–58 (mean age 30±9 years) with no evidence of thyroid disease were tested as the control for anti-eye muscle antibody measurement.

**Case Report**

A 70-year-old man was referred to our hospital in December, 1990 because of edema of the left eyelid, exophthalmos and visual disturbance in his left eye. Prior to this, he had been receiving lithium carbonate (200 mg daily) for 20 years because of mania. He had no symptoms suggestive of hyperthyroidism. In August, 1989 he had noticed photophobia, overflow of tears, conjunctival injection and periorbital edema in his left eye. Ophthalmological treatments (eye drops) gave no relief. Diplopia and an increase in unilateral exophthalmos also developed in May, 1990. In October, 1990 he complained of the loss of visual acuity in the left eye. On physical examination in December 1990, his blood pressure was 120/70 mmHg and his pulse rate was 76/min. and regular. He was 154cm tall and weighed 65 Kg. Left unilateral exophthalmos, periorbital edema and conjunctival chemosis were observed. Movements of the left eye were limited in all directions. Visual acuity was 20/20 in the right eye but only perception of hand movement was possible with the left eye. The proptosis was 20 mm for the left eye and 17 mm for the right eye with a base line of 102 mm measured with a Hertel ophthalmometer. Intraocular pressure was 19 mmHg in the left and 18 mmHg in the right. His eye changes were classified as class VI according to the American Thyroid Association classification [16]. The thyroid gland was not palpable. His voice was hoarse. No abnormality of the heart, chest of abdomen was

**Fig. 2.** The biopsy specimen of the enlarged left medial rectus muscle before pulse therapy, showing marked mononuclear cell infiltration around the vessel and interstitial edema. a, HE staining 40×; b, HE staining 200×.
detected. The Achilles tendon reflex showed a slow return. Laboratory studies revealed a normal hemogram and normal values in urinalysis and biochemical tests. Thyroid function studies revealed primary hypothyroidism. Serum free T₃ was 2.4 pg/ml and free T₄ was 4.4 pg/ml. TSH was 35.39 μU/ml. Thyroglobulin was 223 ng/ml. Neither anti-thyroglobulin antibody nor antimicrosomal antibody was detected. Anti-TSH receptor antibodies were positive. The TSH binding inhibitor immunoglobulin (TBII) level was 32.8% and thyroid stimulating antibody (TSAB), 831%. TSBAB was not detected (−20.6%). ¹²³I uptake was 25.7% at 5 h and 22.1% at 24 h. The plasma lithium level was 1.08 mM (therapeutic range; 0.3–1.5).

A computerized tomographic scan of the orbit showed enlargement of the left upper, medial and inferior rectus muscles. MRI also showed enlargement of these eye muscles, and their signal intensities in a short inversion time inversion recovery (STIR) image were increased, suggesting edematous change in the eye muscles (Fig. 1). The eye muscles in the right eye were also enlarged to some extent and their signal intensity in STIR was increased. The left optic nerve was compressed by the enlarged eye muscles. The biopsy specimen of the enlarged left medial rectus muscle before pulse therapy showed marked mononuclear cell infiltration, interstitial edema and some degeneration of muscle fibers (Fig. 2a, 2b). From the immunohistological examination infiltration of both CD4⁺T cells and CD8⁺T cells was observed in the muscle. Both CD45RA⁺ and CD45RO⁺ cells were present.

The patient was treated with supplementation of levothyroxine (from 25 μg to 100 μg daily) and given four cycles of methylprednisolone pulse

![Clinical course of the patient](image)

**Fig. 3.** Clinical course of the patient. EMAB index: Anti-eye muscle antibody activity is expressed as ratio of density of 64 kDa band obtained by chromatoscopying to that of 66 kDa band which is always stained even with sera from normal subjects. The dotted line represents the upper limit of normal (mean + 2SD for 25 normal subjects).
therapy (1 g daily intravenous injection of methylprednisolone for three successive days a week as a cycle). The effects of treatment and changes in various immunological and biochemical parameters are summarized in Fig. 3. Periorbital edema was markedly diminished after the first cycle of pulse therapy and proptosis improved to 17 mm after the second cycle of the therapy. At the end of the fourth cycle of the therapy periorbital edema and chemosis completely disappeared, although, unfortunately, his visual acuity did not improve. A moderate decrease in the dimension and intensity of the affected muscle was observed in orbital MRI (Fig. 1). After pulse therapy, 20 mg prednisolone was given daily for one month and then tapered off. Prednisolone was discontinued at the end of August, 1991. There have been no relapse of any eye symptoms to this time. TBII and TSAB have not been detected in his serum since 3 months after the pulse therapy.

From Western blotting studies it was shown that the serum contained several antibodies to rat eye muscle membranes at 64, 60 and 48 kDa (Fig. 4). The binding activity, expressed as the ratio of the intensity of positive to that of control band, markedly diminished after pulse therapy for all three antibodies.

Discussion

The occurrence of hypothyroidism in the presence of TSAB may be due to concomitant destructive autoimmune thyroiditis of the administration of lithium for manic depressive disease. Lithium has been reported to inhibit the release of thyroxine from the thyroid glands [17]. Moreover, lithium has been reported to affect the immune system [18, 19]. Weetman et al. [18] demonstrated that lithium increased immunoglobulin synthesis, while Wilson et al. [19] reported an increased IL-2 production and inhibition of cyclic AMP production of peripheral blood mononuclear cells by lithium. Indeed, patients on lithium had a high incidence of anti-thyroid antibodies (20–24%) compared to both patients receiving some other forms of treatment for their depression (7.5%) [20], and normal subjects (10–14%) [21]. Segal et al. [22] and Thompson et al. [23] reported the development of TAO during lithium therapy. Therefore, lithium might have initiated the TAO as well as hypothyroidism in the present case.

As shown in Table 1, most of the patients reported with hypothyroid Graves' disease in the literature had anti-TSH receptor antibodies; 10 of 19 patients had long acting thyroid stimulator (LATS) [10, 24–30], 9 of 12 patients had TBII [2, 31–35] and all 9 patients had TSAB [2, 32–36]. No patient had TSBAB. Although these results suggest a positive relation between ophthalmopathy and anti-TSH receptor antibodies, especially TSAB, there are conflicting reports that TBII do not correlate to the eye disease in Graves' disease [37]. Therefore, the role of anti-TSH receptor antibodies in the development of ophthalmopathy

is still unclear.

This is the first report of serial examination of anti-eye muscle antibodies by Western blot analysis in hypothyroid Graves' disease. The results suggest a relationship between these antibodies and ophthalmopathy in hypothyroid Graves' disease. In recent years, antibodies to a 64 kDa protein in porcine eye muscle [7, 9] and in human eye muscle [6, 8] have been reported in TAO. However, Ahmann et al. [7] and Weightman et al. [9] found that normal sera also bound to a 64 kDa protein and argued against the pathological significance of this protein. Conversely, Salvi et al. [6] reported that 50% of patients with TAO, but no normal subjects, have antibodies against a 64 kDa protein. They further reported that the antibodies also bound to thyroid tissue membranes. More recently Dong et al. [38] reported a cDNA clone encoding a novel 64 kDa protein in the thyroid, and mRNA for this protein was detected in both thyroid and eye muscle, but not in the skeletal muscle in Northern blot analysis. Preliminary studies suggest that this is the same protein as that reported by Salvi et al. [39]. In the present case, we showed the existence of an antibody to 64 kDa protein(s) of rat eye muscle membrane preparations. On the other hand no antibody to rat 64 kDa protein was found in any of 25 normal subjects (Hiromatsu et al., unpublished observation). Moreover we quantified the eye muscle antibody level in serum with a chromatoscanner and showed that anti-eye muscle antibody activity markedly decreased one month after prednisolone pulse therapy, suggesting that the antibody to 64 kDa may be a good clinical marker for the development of ophthalmopathy. Interestingly, a high prevalence of antibodies to the 64 kDa eye muscle membrane antigen in patients receiving lithium therapy has been found in the studies of How and Wall (personal communication). In the present study, antibodies to 60 kDa and 48 kDa eye muscle membrane were also present in serum before steroid pulse therapy and disappeared after steroid pulse therapy. However, the identity of antigens and the significance of these antibodies are unknown. These antibodies have not been reported in TAO.

In conclusion, although the nature of the 64 kDa eye muscle membrane antigen, the specificity of the antibody to this antigen and the role of this antibody in the mechanism of the development of TAO need to be further studied, the quantitative measurement of anti-eye muscle antibodies may be useful in evaluating the activity of TAO. The role of lithium in the development of ophthalmopathy is ready to be evaluated.
