Abstract: This study was undertaken to investigate whether the concentration of carbonic anhydrase isoenzyme I (CA-I) in canine feces and urine is useful as a temporary marker of occult blood. Concentrations of CA-I were measured by enzyme-linked immunosorbent assay (ELISA). Fecal CA-I concentrations in 113 healthy beagle dogs (50 male and 63 female) of various ages ranged from 4.3 to 16.7 ng/g feces (mean; 7.0 ± 2.9 ng/g feces). One milliliter of blood from 3 healthy beagle dogs was found to contain 1,047, 1,062 and 1,150 µg CA-I. The fecal CA-I concentrations of dogs receiving intragastric infusions of autologous blood (10 ml) were very low. However, the fecal CA-I concentrations of dogs receiving infusion of autologous blood (5 ml) into the ascending colon were very high. Detection of fecal CA-I would be useful for identifying dogs with hemorrhaging of the large intestine. Of 55 urinary samples collected from healthy beagle dogs by catheter, chemical tests for occult blood were negative in 44, but CA-I concentrations ranged from 1.8 to 12.6 ng/ml (mean; 6.9 ± 5.4 ng/ml) by ELISA. The CA-I concentrations of the other 11 samples, which tested positive for occult blood on chemical testing, ranged from 41.2 to 525.0 ng/ml by ELISA. Although CA-I is not a specific marker of erythrocytes, CA-I may be used to detect occult blood in canine feces and urine until a specific immunological test kit using antibody for Hb is developed.

Key words: canine feces, carbonic anhydrase isoenzyme I (CA-I), occult blood

Introduction

In human medicine, chemical [9, 14] and immunological [1, 17] tests for occult blood are currently employed in early screening for hemorrhagic diseases of the intestine, such as tumors or cancer. Immunological tests for occult blood are specific for hemoglobin (Hb) derived from erythrocytes [24]. Chemical tests
for fecal occult blood are sensitive, but false-positive reactions can be induced by the blood present in ingested meat and fish [12, 25]. In veterinary medicine, including the field of drug safety evaluation, the development of specific immunological tests using anti Hb antibodies for occult blood in various animals is indispensable. In dogs, a few reports have described the usefulness of immunological tests for fecal occult blood [10, 11], but chemical tests are currently used for the detection of fecal occult blood [7]. Because erythrocytes contain both Hb and carbonic anhydrase isoenzyme I (CA-I) [11] as major proteins, the purification of canine Hb from lysate and the preparation of antibody for canine Hb are very difficult. When compared with Hb, it is relatively simple to prepare a specific antibody for canine CA-I.

Although CA is present in the tissues of the intestinal and the urinary organs [20], and small amounts of CA-I are probably secreted into feces and urine, CA-I may be useful for detecting occult blood in various animals until specific immunological tests for occult blood are developed.

This paper describes an enzyme-linked immunosorbent assay (ELISA) for the detection of CA-I as a temporary marker of occult blood in feces and urine from healthy beagle dogs.

**Materials and Methods**

**Dogs, blood, feces and urine**

Eleven healthy beagle dogs (5 males and 6 females; age, 12–13 months) were kept in the experimental animal facilities of the Research Institute of Biosciences at Azabu University (temperature, 20 ± 2°C; relative humidity, 50 ± 10%; 12/12 light/dark cycle (6:00–18:00); air exchange occurred 13 times per hour) and were used in this study. The beagle dogs were fed Clea CD-5 dog feed (Clea Japan, Inc., Tokyo, Japan), and were allowed free access to water. Heparinized blood for isolation and quantification of CA-I and feces for determination of antibody for canine Hb were very difficult. When compared with Hb, it is relatively simple to prepare a specific antibody for canine CA-I.

For immunological quantification of fecal CA-I by ELISA, feces samples were treated and stored within 6 h of collection. One gram of feces was mixed with 1 ml of distilled water, after which 1 ml of 0.02 M PBS containing 0.2 % sodium azide was added. The supernatant obtained by centrifugation (1,600 × g for 10 min) was stored immediately at –80°C until use.

In order to quantify the amount of CA-I in feces from healthy beagle dogs of various ages, feces were collected from 113 beagle dogs (50 males and 63 females; age, 3–24 months), kept in isolators at the Breeding Division of Hongo Beagle Farm, Kitayama Labes Co., Ltd. (Yamaguchi, Japan) at a temperature of 23 ± 2°C, a relative humidity of 55 ± 10%, and a 12/12 light/dark cycle (6:00–18:00) with air exchange occurring at least 12 times per hour. Dogs were fed a DS-E diet (Oriental Yeast Co., Ltd., Tokyo, Japan), and were allowed free access to water. For immunological quantification of CA-I, feces samples were treated and stored as described above.

In order to quantify the amount of CA-I in urine from healthy beagle dogs, urine was collected by catheter from 55 beagle dogs (28 males and 27 females; age, 6–24 months) kept in isolators at the Breeding Company, CSK Co., Ltd., (Nagano, Japan) (44 dogs) and in the experimental animal facilities at Azabu University (11 dogs). Urine was used for both quantification of CA-I by ELISA and detection of hemoglobin by chemical testing. Urine was also mixed with 0.1% sodium azide and stored at –80°C until use.

All experiments conformed to the Japanese regulations on animal care and use, based on the Guidelines for Animal Experimentation (Japanese Association for Laboratory Animal Science, JALAS, 1987), and were approved by the Institutional Animal Care and Use Committee of CSK Co., Ltd. and the Animal Research Committee of Azabu University.

**Isolation of canine CA-I**

Canine CA-I was isolated using the method of Nishita et al. [16]. Briefly, the CA fraction was obtained from lysate of washed canine erythrocytes using the chloroform-ethanol denaturation method, which is used for the preparation of CA in a number of other mammals.
Hb was removed as a precipitate and the supernatant was then collected and dialyzed against 10 mM Tris-HCl buffer (pH 8.0). CA-I was isolated from the supernatant by liquid chromatography, as described by Funakoshi and Deutsch [6]. For fast protein liquid chromatography (FPLC; Amersham Biosciences, Uppsala, Sweden), a HiLoad 16/10 Q sepharose column (Amersham Biosciences) was used for ion-exchange chromatography, a Mono P HR5/20 column (Amersham Biosciences) was used for chromatofocusing and a Superdex 200 16/60 column (Amersham Biosciences) was used for gel filtration.

CA enzyme activity and hemoglobin content of each fraction on FPLC were detected by p-nitrophenyl acetate [4] and 2,2'-azino-di-(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS; Zymed Laboratories, South San Francisco, CA, USA), respectively.

Anti canine CA-I antibody
A New Zealand rabbit was initially immunized subcutaneously with 1 ml of CA-I emulsion prepared with Freund’s complete adjuvant. The rabbit subsequently received ten further injections of CA-I solution alone. Serum was collected at 7 days after the final immunization and was stored at –80°C until needed.

IgG antibody was obtained from this antiserum by affinity chromatography on a Protein A column (Amersham Biosciences) [8]. Subsequently, specific IgG antibody against canine CA-I was isolated by affinity chromatography using a HiTrap NHS-activated HP gel coupled with canine CA-I. The specific IgG antibody to canine CA-I was used for ELISA. Peroxidase (Sigma-Aldrich Fine Chemical, St Louis, Mo, USA)-conjugated IgG antibody was prepared by the method of Nakane and Kawaoi [15]. This peroxidase-conjugated IgG antibody was used for ELISA.

Quantification of proteins
Isolated CA-I was quantified by the method of Bradford [3] using Coomassie brilliant blue G-250. Rabbit anti canine CA-I IgG antibody was quantified using a Bio-Rad Protein Assay Kit (Bio-Rad Laboratories, Hercules, CA, USA).

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and western blotting
SDS-PAGE and western blotting were performed using the methods of Laemmli [13] and Towbin et al. [23], respectively. After SDS-PAGE for isolated CA-I, the gels were stained with Coomassie brilliant blue R-250.

The specificity of the rabbit anti canine CA-I IgG antibody was confirmed by western blotting analysis followed by SDS-PAGE.

ELISA for CA-I
ELISA for CA-I was carried out using the sandwich method described by Yamamoto et al. [26]. Rabbit anti canine CA-I IgG antibody was adjusted with 0.05 M sodium hydrogen carbonate buffer (pH 9.6) to 10 µg/ml for use as the coating antibody. The coating antibody (100 µl/well) was incubated at 37°C for 1 h in an ELISA plate (Nalge Nunc International, Rochester, NY, USA). Next, 1% bovine serum albumin (BSA; Wako Chemical Co., Ltd., Osaka, Japan) in 0.05 M sodium hydrogencarbonate buffer (pH 9.6) was added to all the wells at 300 µl/well to block any unadsorbed binding sites (4°C, overnight). After washing, a known concentration of CA-I or samples were added at 100 µl/well and the plates were incubated at 37°C for 1 h. The peroxidase-conjugated rabbit anti canine CA-I IgG antibody, adjusted with PBS to 2.5 µg/ml, was added to all the wells at 100 µl/well and was allowed to react at 37°C for 1 h. Substrate at 0.05% in 0.05 M citrate buffer (pH 4.2) was added at 100 µl/well. The results were determined by measuring the absorbance at 415 nm with an immuno plate reader.

Experimental models for detection of CA-I in feces
Three healthy beagle dogs each received 5 or 10 ml of autologous blood infused from a syringe via a catheter into the stomach. After 1 week, the same 3 healthy dogs each received 1 or 5 ml of autologous blood similarly infused into the ascending colon. Samples were collected from the first to the third spontaneous defecations for detection of CA-I. Feces obtained from these dogs prior to infusion of autologous blood were used as controls. Feces (1 g) were treated as described above.

In order to assay changes in CA-I antigenicity in feces, 1 g of feces from 2 healthy dogs was mixed with 100 µl of blood and was allowed to stand at room temperature for 12 h. CA-I was then extracted as above, and its antigenicity was assessed by ELISA.

Chemical test for urinary occult blood
Occult blood in urine was detected using Multistix SG-L (Distributed by Sankyo Co., Ltd., Tokyo, Japan).

### Results

**Isolation of canine CA-I and anti canine CA-I antibody**

CA-I was isolated from the lysate of canine erythrocytes by liquid chromatography using FPLC (Fig. 1A). In western blotting, anti canine CA-I antibody formed a single band with isolated canine CA-I and with a 30-kDa protein in lysate of canine erythrocytes (Fig. 1B).

**Concentrations of CA-I in blood**

As shown in Table 1, CA-I concentrations in blood from 3 apparently healthy beagle dogs ranged from 1,047 to 1,150 µg/ml blood.

**Antigenicity of CA-I**

The antigenicity of canine CA-I stored in feces at room temperature for 12 h did not change (Table 2).

**Concentrations of CA-I in feces from healthy dogs**

The fecal CA-I concentrations in 113 healthy beagle dogs of various ages are shown in Table 3. Fecal CA-I concentrations ranged from 4.3 to 16.7 ng/g feces (mean; 7.0 ± 2.9 ng/g feces).

**Detection of CA-I in feces in experimental models of digestive tract bleeding**

The fecal CA-I concentrations of dogs that received intragastric infusion of autologous blood were very low (Table 4). However, the fecal CA-I concentrations of the dogs that received infusion of autologous blood (5 ml) into the ascending colon were very high, as shown in Table 4.

**Concentrations of CA-I in urine**

Urinary samples from 44 of 55 dogs were negative by chemical testing (detectable limit 150 ng hemoglobin/ml). As shown in Table 5, CA-I concentrations in the negative urinary samples ranged from 1.8 to 12.6 ng/ml (mean; 6.9 ± 5.4 ng/ml) by ELISA. On the other hand, urinary samples from the other 11 dogs were positive by chemical testing. The CA-I concentrations of 6 urinary samples that were 2+ on chemical testing were 41.2–98.0 ng/ml, while the CA-I concentrations of 5 samples that were 3+ on chemical testing

Discussion

In human medicine, chemical tests for fecal occult blood have largely been replaced by immunological methods [19]. However, the development of useful methods that allow specific detection of internal bleeding in dogs and another animals remains at an early stage.

Although we have previously reported the usefulness of immunological tests using specific anti canine Hb antibody for occult blood in dogs [10, 11], the preparation of anti canine Hb antibody is currently very difficult. Therefore, nonspecific chemical tests [12, 25] are generally employed to detect fecal occult blood in dogs, and these techniques are still used in for a variety of purposes, such as drug safety evaluation, or in veterinary clinics.

CA-I is not a specific marker of erythrocytes, as it is present in the tissues of the intestinal and urinary organs [20] and it may be secreted from these organs into their respective tracts. Unfortunately, it is impossible to determine the origin of CA-I. However, CA-I may be used to detect occult blood in canine feces until a specific immunological test kit using antibody for Hb is developed. This is because fecal CA-I concentrations in healthy dogs were very low, while fecal CA-I concentrations in dogs that received infusion of autologous blood into the ascending colon were found to be very high. When 3 dogs were infused 1 ml of autologous blood, CA-I was not detected in feces, probably because feces containing the infused blood were not collected in test samples. Detection of fecal CA-I would
thus be useful for identifying dogs with hemorrhaging of the large intestine.

The antigenicity of human Hb changes as a result of digestive enzymes or fecal bacteria [5]. However, when feces samples were mixed with blood and allowed to stand at room temperature for 12 h, the reactivity of canine CA-I did not change. Consequently, CA-I in feces may be used as an antigen for immunological tests.

Physiological bleeding into the intestine is seen even in healthy humans [2] and dogs [11]. Such internal bleeding should be carefully considered in the clinical application of immunological tests for fecal occult blood in dogs [10]. Eleven of 58 urinary samples from apparently healthy beagle dogs were positive by chemical testing and showed markedly increased CA-I by ELISA. This is thought to have been due to scratching of the ureter mucous membrane when the tube was inserted to collect urine.

Although sensitive methods, such as ELISA, are required in the quantification of CA-I in dogs, CA-I concentrations are a useful temporary marker for occult blood. In the future, it will be necessary to develop quantitative methods for occult blood using Hb as a specific marker.

Acknowledgments

We thank CSK Co., Ltd., for the supply of canine urine.
