Abstract : A 43-year-old man, a regular drinker, developed a pseudocyst in the pancreatic tail as a result of acutely worsening chronic pancreatitis. Because the pseudocyst, 10 cm in diameter, did not disappear despite conservative treatment, an internal drainage stent was placed transgastrically under endoscopic ultrasound (EUS) guidance. However, cyst infection occurred, and EUS-guided drainage was performed, when the gallbladder was punctured inadvertently. Immediately a nasocystic drain was placed in the gallbladder. Owing to this timely measure, only mild and localized peritonitis developed. Conservative treatment with fasting and an antibiotic was administered, and peritonitis subsided quickly. On the same day, another nasocystic drain was placed for the pancreatic pseudocyst, and it disappeared. As far as we know, this is the first case in which gallbladder puncture was inadvertently performed during EUS-guided drainage of a pancreatic pseudocyst.

Key words : gallbladder puncture, pancreatic pseudocyst, EUS-FNA, EUS-guided drainage, complication

INTRODUCTION

A pancreatic pseudocyst is a nonepithelial cyst formed after acute deterioration of acute and chronic pancreatitis, and injury to and resection of the pancreas. It often resolves spontaneously with conservative treatment. If it does not, complications, such as cyst infection and bleeding and rupture of the digestive tract, may ensue, threatening life. Therefore, in the past it has been removed surgically or drained percutaneously. Recently, with the advances in endoscopic therapy, endoscopic transmural drainage has become possible¹⁻³). However, the problem with this method using a conventional endoscope was that puncture under direct vision had to be blind puncture, causing complications, such as bleeding and digestive tract perforation. In recent years, endoscopic ultrasound (EUS)-guided transmural drainage has been developed, and its safety and usefulness are estimated to be superior to those of the conventional method⁴⁻¹²).

Complications of EUS-guided pancreatic pseudocyst drainage are divided into two groups: early complications associated with surgical techniques, and late complications occurring in the course of recovery. Common early complications include bleeding and perforation, and late complications are mostly cyst infections due to obstruction of a drainage tube⁴). Kruger *et al.*⁵) reported that no early complications occurred in the 35 patients they had seen, and Giovannini *et al.*⁶) reported that only 1 (2.9%) of their 35 patients developed mild pneumoperitoneum, which resolved quickly. Vosoghi *et al.*⁷), however, reported that in 1 (7%) of their 14 patients, bleeding occurred 2 days after the procedure, requiring surgery. Thus, in performing EUS-guided drainage, although it is regarded as safer than the conventional method, the knowledge of how to prevent and how to cope with complications is important. We inadvertently injured the gallbladder of a patient with pancreatic pseudocyst during EUS-guided drainage. We report here how we coped with it and how it could have been prevented.

CASE REPORT

A 43-year-old man, a regular drinker, presented to our hospital complaining of an abdominal pain in April 2001. Because a CT scan showed a 10-cm pseudocyst and bleeding into the cyst in the pancreatic tail, he was hospitalized and underwent conservative treatment for 56 days. However, the pseudocyst did not reduce, and so he was rehospitalized to undergo EUS-guided drainage in December 2001. On admission, although there was no abdominal pain, and a blood test showed no inflammation reaction or elevated tumor marker, CT scan showed a 10-cm pseudocyst in the pancreatic tail (Fig. 1); therefore, EUS-guided cystogastrostomy was performed on the fifth hospital day. A curved linear-array echo endoscope (FG-36UX; Pentax Corp., Tokyo, Japan) was inserted into the stomach, and an

Fig. 1. Contrast-enhanced abdominal CT image. A dilated pancreatic duct and a 10 cm diameter cyst were seen in the pancreatic tail (arrow). The cyst was considered a pseudocyst because there was no evidence of malignancies, such as mural nodules at the cyst wall or a tumor in the pancreas.

ultrasound imaging device attached to it (EUB-6000 ; Hitachi Ltd., Tokyo, Japan) depicted a pancreatic pseudocyst as a uniform granular echo pattern (Fig. 2). After the pseudocyst was punctured with a 19G needle (ECHOTIP ; Wilson-Cook Medical Inc., Osaka, Japan) without electricity, the stomach wall (upper gastric body) and cyst wall of the puncture site were stretched with a dilator, and a Zimmon Biliary Stent 7Fr, 4 cm (Wilson-Cook Medical Inc., Osaka, Japan) was placed (Fig. 3). However, the pseudocyst did not resolve ; the temperature and inflammation reaction increased, suggesting cyst infection due to stent clogging. The patient's condition remained unimproved with conservative treatment, and on the 34th hospital day, EUS-guided nasocystic drainage (ENCD) of the pseudocyst was performed transgastrically. Before puncture, transgastric EUS had confirmed a cyst-like structure whose interior was visualized as two layers, i.e., an echoic and anechoic areas (Fig. 4). This cyst-like structure was punctured under EUS guidance, and a 5 Fr endoscopic nasobiliary drainage (ENBD) tube (Flexima ; Boston Scientific Corp., Tokyo, Japan) was placed. Fluoroscopic observation of the patient in the supine position revealed the tube in the right side of the abdomen, from which it was evident that the gallbladder had been punctured, not the pancreatic pseudocyst (Fig. 5). Careful review showed that the puncture site was in the lower gastric body when it should have been in the upper gastric body. The tube was left in the gallbladder so that bile would not leak into the abdominal cavity causing bile peritonitis. The pseudocyst was drained by reinserting the EUS and placing a 5Fr ENBD tube (ENBD-5 ; Wilson-Cook Medical Inc., Osaka, Japan) in the cyst. The fluid was milky white.

Fig. 2. EUS image. The pancreatic pseudocyst showed no wall thickening and had a granular echo pattern with relatively uniform inner echo density.

Fig. 3. Endoscopic image. A stent was inserted into the pancreatic pseudocyst from the posterior wall of the greater curvature of the stomach.

Fig. 4. EUS image. A cyst-like structure with the interior visualized as two layers.

Fig. 5. Plain abdominal roentgenogram in the supine position. The nasocystic drain (broad arrow) is located away from the stent (arrow) placed in the pancreatic pseudocyst. The dotted arrow indicates the ultrasonic endoscope used.

Abdominal roentgenogram taken on the following day showed that the tip of the tube in the gallbladder had moved slightly. A CT scan performed 2 days later confirmed that it had slipped out of the gallbladder into the abdominal cavity (Fig. 6). Three days later, that part of the tube that had slipped out of the gallbladder was removed under fluoroscopic observation, taking care that the rest of the pseudocyst did not fall out. To prevent leakage of gastric juice from the puncture

Fig. 7. Plain abdominal CT image. The pancreatic pseudocyst subsided considerably, and inside it was the tube that had been placed (arrow).

site into the abdominal cavity, a tube was inserted into the stomach through the nose. Continuous administration of antibiotics during fasting controlled the inflammatory reaction. A CT scan performed 7 days later showed that the pseudocyst subsided considerably (Fig. 7). A restricted diet was started on the 48th hospital day, 14 days after the first drainage, and the ENCD tube in the pseudocyst was removed on the 54th hospital day, 19 days after the first drainage. Even after the tube was removed, the inflammatory reaction remained controlled, and a CT scan showed no infection or enlargement of the cyst, and so the patient was released from the hospital on the 65th hospital day.

DISCUSSION

Grimm *et al.*⁸⁾ first reported EUS-guided transmural drainage of pancreatic pseudocysts in 1992. Before then, pseudocysts had been punctured and drained under direct vision using a regular endoscope. The traditional method, however, involved blind puncture and was inapplicable to patients without a luminal bulge in the digestive tract⁹⁾. Furthermore, there were risks of bleeding and perforation as complications. The new technique, using the EUS image as a guide, is safe as many investigators report⁴⁻¹²⁾ and permits puncture in real time. Vosoghi *et al.*⁷⁾, who reviewed the complication rates of various treatments, reported the highest safety of EUS-guided transmural drainage as follows: the complication rates of surgical treatment, percutaneous drainage, transpapillary drainage, endoscopic puncture drainage under direct vision and EUS-guided puncture drainage were 28%, 18%, 12%, 15% and 1.5%, respectively.

Thus, EUS-guided transmural drainage is the first-choice treatment for patients with pancreatic pseudocyst, if they can tolerate the endoscopic procedure. However, although its complication rate is lower than that of any other treatment, those who perform this procedure should have a thorough knowledge of the complications that can arise from it. The early complications associated with this technique include bleeding, perforation and intraperitoneal emphysema^{5,7,10-12)}. Binmoeller *et al.*³⁾ reported a case (4.1%) of inadvertent puncture of the gallbladder during the attempted puncture of a pancreatic pseudocyst under direct vision. In their case, bile leaked, and a surgical operation was required. Fortunately, in our case, no surgery was needed. After inadvertent puncture of the gallbladder and subsequent stretch of the puncture site, a small amount of bile leaked into the abdominal cavity. However, an ENCD tube reduced the pressure in the gallbladder, eventually stopping the bile leak and eliminating the need for surgery. The factors considered to have led to inadvertent puncture of the gallbladder in this case are: 1) The gallbladder that enlarged because of long fasting was unusually visible from the stomach. 2) Because there was a large amount of debris in the gallbladder, it was mistaken for an infected pancreatic pseudocyst (pancreatic abscess). 3) Because the entire procedure was performed with the patient in the left lateral decubitus position, the

pancreatic pseudocyst and gallbladder overlapped on the x-ray fluoroscopic image. To prevent similar complications, it is essential to accurately identify a pancreatic pseudocyst on EUS images and carefully choose a puncture site in the stomach on endoscopic images. Moreover, the pancreatic pseudocyst should also be confirmed under X-ray fluoroscopy with the patient's position changed from left decubitus, taken when the endoscope is inserted, to supine.

In conclusion, EUS-guided transmural drainage of pancreatic pseudocysts is safer than the blind puncture technique using a regular endoscope. However, endoscopists should realize again that because many different objects surrounding the digestive tract are visible, the target can be mistaken, leading to a complication. Those who perform this procedure need to fully understand the possibility of a complication such as ours, and keeping in mind how to cope with it, they should strive for accuracy in diagnosis and every aspect of this procedure.
