Received October 9, 2001; Accepted February 12, 2002

The application of supercritical carbon dioxide (SC-CO2) extraction to waste powder derived from sweetpotato roots with orange flesh in a food processing factory was examined. The contents of antioxidants, β-carotene, α-tocopherol and chlorogenic acid, remaining in the waste powder after SC-CO2 extraction under different conditions were determined by HPLC. At a constant extraction pressure, the extraction yield of β-carotene from the waste powder was highest at 40°C, decreased at 60°C and decreased further at 80°C; in contrast, the α-tocopherol yield did not vary under different temperature conditions. At a constant extraction temperature, increasing extraction pressure increased the extraction yields of both β-carotene and α-tocopherol. Under the conditions tested, the yields of β-carotene (95.1%) and α-tocopherol (76.8%) were highest at 40°C and 35 MPa. Little chlorogenic acid was extracted from waste powder. The β-carotene remaining in the waste powder after SC-CO2 extraction correlated well with its color value of a*

Keywords: sweetpotato, waste, powder, supercritical carbon dioxide, β-carotene, α-tocopherol, chlorogenic acid

Sweetpotato is a very important upland crop in southern Japan and has been cultivated for table use and production of starch and liquor. Recently, Sunny Red, a new sweetpotato cultivar with orange flesh, was released for the utilization of its dried powder as raw materials for noodles, breads and confectionery (Kumagai et al., 1998). The main pigment in Sunny Red’s storage roots is β-carotene (Takahata et al., 1993; Okuno et al., 1998); the roots also contain tocopherols, mainly α-tocopherol (Okuno et al., 1998). These compounds are known to be hydrophobic antioxidants. Beta-carotene was shown to have many biological activities including antitumor-promoting activity (Murakoshi et al., 1992) and inhibition of cellular DNA breakage (Hiramoto et al., 1999). It has also been reported that consumption of a diet containing antioxidants such as β-carotene and tocopherols may reduce the plasma level of lipid peroxide (Singh et al., 1995). Sweetpotatoes also contain chlorogenic acid, which was shown to have such activities as antioxidative activity (Azuma et al., 1999), antineoplastic effects in mice (Kapil et al., 1995) and suppressing melanogenesis in cultured cells (Shimozono et al., 1996).

In the production of sweetpotato powder, waste powder was discarded, and this may impact the environment. Therefore, utilizing the waste powder can contribute to the production of valuable compounds and materials and the reduction of environmental impact.

A supercritical fluid, which is used above the critical temperature and critical pressure, has properties between gas and liquid phases. Extraction with supercritical carbon dioxide (SC-CO2) has been widely applied in the area of food science and technology including applications such as extraction of oils (Stahl et al., 1984), carotenoid pigments (Degnan et al., 1991; Spanos et al., 1993) and a pesticide (Ambrosino et al., 1999) from plant materials. This technique has the following advantages compared with conventional processes of extraction with organic solvents and of distillation. Compounds extracted with SC-CO2 have no toxic solvent residue because SC-CO2 extraction does not require organic solvents and SC-CO2 is itself non-toxic. The low temperature in SC-CO2 extraction reduces thermal degradation of labile compounds and energy costs. CO2 is also inexpensive and readily available; it can be collected and recycled after extraction, reducing its release into the environment. As described above, there are many reports on the use of SC-CO2 for extracting natural products from primary materials, including seeds, leaves and storage roots. In contrast, few studies have focused on the applicability of SC-CO2 extraction for utilizing wastes and by-products discarded in food industries as sources of important compounds or materials.

The objective of this study was to investigate the potency of extraction with SC-CO2 to utilize the waste powder derived from a process of powder production from a new sweetpotato cultivar, Sunny Red. The effects of SC-CO2 conditions on extraction of the important compounds, β-carotene, α-tocopherol and chlorogenic acid, from the waste powder were examined.

Materials and Methods

Materials As standards for HPLC analysis, β-carotene

E-mail: sokuno@affrc.go.jp
was purchased from Sigma (St. Louis, MO), and chlorogenic acid and α-tocopherol from Wako Pure Chemical Industries (Osaka). The waste powder from Sunny Red was a generous gift from a local food manufacturing company. Its moisture level was determined to be 9.6% (w/w) by heating a sample (5 g) at 105°C for 2 h in an oven.

**SC-CO₂ Extraction** Extraction experiments were performed on an SPE-1000 supercritical carbon dioxide extraction apparatus (Kobe Steel, Hyogo). The extraction vessel was 70 mm i.d. and 135 mm deep. One hundred grams (218 cm³) of the waste powder was placed in an extraction vessel for each condition. Carbon dioxide was supplied into the extraction vessel, and compressed and heated. Soon after the pressure and temperature reached the desired values, carbon dioxide was passed through a collection tube at 5 l/min for 2 h and an extract was collected.

The waste powder before SC-CO₂ extraction and the powder residues after extraction were used in the experiments described below.

**Quantification of β-carotene and α-tocopherol** One milliliter of ethanol containing 0.1% (w/v) butylated hydroxytoluene (BHT) was added to 100 mg of a powder sample in a centrifuge tube with a cap and mixed by a vortex mixer. To this mixture, 3 ml of n-hexane containing 0.05% (w/v) BHT was added followed by further mixing. After adding 1 ml of water and mixing, the mixture was centrifuged at 2000 rpm for 5 min. The upper layer of the supernatant was collected and 3 ml of n-hexane containing 0.05% (w/v) BHT was added to the rest. After re-extraction, the resultant upper layer was combined and evaporated under a stream of nitrogen gas. The extract was redissolved in 1 ml of tetrahydrofuran containing 0.05% (w/v) BHT and filtered through a membrane filter (DISMIC-13HF; pore size: 0.2 µm; ADVANTEC, Tokyo). A 10-µl portion of the filtrate was injected into the HPLC system and eluted as described below. The HPLC system consisted of a Model LC-10AT pump, a Model SIL-10AXL autoinjector, a Model CTO-10AC column oven, a Model SPD-M10A VP photodiode array UV-VIS detector and a Model RF-10A spectrofluorometric detector (Shimadzu, Kyoto). A 10-µlportion of the filtrate was injected into the HPLC system and eluted as described below. The photodiode array detector at 460 nm detected the alpha-tocopherol was purchased from Sigma (St. Louis, MO), and chlorogenic acid and α-tocopherol from Wako Pure Chemical Industries (Osaka). The waste powder from Sunny Red was a generous gift from a local food manufacturing company. Its moisture level was determined to be 9.6% (w/w) by heating a sample (5 g) at 105°C for 2 h in an oven.

**Results and Discussion**
In processes of sweetpotato powder production in a food manufacturing company, sweetpotato roots are sliced without peeling, dried, milled and passed through a sieve (mesh size: 180 µm). The material remaining on the sieve is waste powder without commercial value and is discarded. This waste powder was used in our experiments.

Table 1 shows the contents of β-carotene and α-tocopherol in the powder residues obtained by treatment with SC-CO₂ under different pressure and temperature conditions. At a constant pressure of 25 MPa, the extraction yield of β-carotene from the waste powder was the lowest at 80°C, and extraction at 40°C was similar to that at 60°C. From the viewpoint of energy costs in an extraction process, the condition at 40°C is more beneficial for β-carotene extraction than that at 60°C. The extraction yields of α-tocopherol were similar under the three temperature conditions. The reason for this difference in the temperature effect on extractability of β-carotene and α-tocopherol is not clear. A co-factor in the waste powder may influence the extractability of α-tocopherol; pure α-tocopherol must be treated with SC-CO₂ in order to examine this possibility. It was also reported that extraction yields were independent of temperature in extraction of crude fat from rice bran (Taniguchi et al., 1987) and of limonoids from citrus seed meals (Ayano et al., 1992); however, the reason was not mentioned. In our experiments, we examined the influence of temperature on the extraction yields of compounds in the waste powder only at 25 MPa. Therefore, it is important to perform extraction experiments under various other pressure conditions.

We next examined the effects of CO₂ pressure on the extraction yields of β-carotene and α-tocopherol. As shown in Table 1, the yields of β-carotene (95.1%) and α-tocopherol (76.8%) were proportions.
highest at 35 MPa. These results revealed that the yields of both compounds increased as the CO₂ pressure increased at a constant temperature of 40°C. This tendency is consistent with that reported for extracting bixin from annatto seeds (Degnan et al., 1991), carotenoids from sweetpotato roots (Spanos et al., 1993) and lycopene from tomato skin (Inakuma et al., 1998). This may be because an increase in SC-CO₂ density with an increasing pressure leads to increased solubility of compounds in SC-CO₂ as described in previous reports. When SC-CO₂ was applied to extract carotenoids from sweetpotatoes, it was reported that 47.0% of the total carotenoid content was extracted from oven-dried sweetpotato powder, and 64.4% was extracted from freeze-dried powder under the condition of 41.4 MPa, 38°C and 1000 l of the total CO₂ volume at 14–18 l/min (Spanos et al., 1993). The particle sizes of these materials were between 250 and 420 μm. In contrast, 95.1% of the β-carotene in the waste powder was extracted under the condition of 35MPa, 40°C and 600 l of the total CO₂ volume at 300 l/h in our experiments (Table 1). The particle size of the waste powder exceeded 180 μm, but we did not perform further fractionation of the powder. The waste powder appeared to be heterogeneous to the naked eye and contained large particles derived from sweetpotato root epidemis. The higher extraction yield of carotenoids in our experiments may be due to the difference in content of small particles or in tissue structures of cultivars used. To clarify the influence of tissue structure on accessibility of SC-CO₂ to the inside of the powder particles, it is important to compare extraction yields of carotenoids from different sweetpotato cultivars and to perform microscopic research on the powder particles.

The chlorogenic acid content in the waste powder before SC-CO₂ extraction was 19.4 mg/100 g and ranged from 17.8 to 19.4 mg/100 g after extraction under the conditions tested (data not shown). This indicates that little chlorogenic acid was extracted with SC-CO₂ in contrast to β-carotene and α-tocopherol. This result may be due to the higher polarity of chlorogenic acid than that of β-carotene and α-tocopherol because SC-CO₂ is thought to behave similarly to hexane. It was also reported that bixin was extracted with SC-CO₂, but norbixin, which is more polar than bixin, was not extracted under the same conditions (Degnan et al., 1991).

Figure 1 shows the relationship between the color value of a* and the β-carotene content of the powder samples treated with and without SC-CO₂ (n=9). The correlation coefficient was 0.987 and was higher than that between the value of L* and β-carotene content (0.486) and that between b* and β-carotene content (0.737) (data not shown). This indicates that removing β-carotene from the powder samples was most closely related to a decrease in the color value of a*. Such a relationship was reported between the color value of the cut surface of raw sweetpotatoes with orange flesh and their β-carotene content (Takahata et al., 1993).

It was recently reported that SC-CO₂ was applied to extract lycopene from tomato skin derived from the production of tomato juice (Inakuma et al., 1998). In that study, tomato skin drying conditions were examined and dried samples were subjected to SC-CO₂ extraction. In general, materials with high moisture content are not suitable for usual SC-CO₂ extraction. In our present study, the waste powder produced in drying processes in a factory was treated with SC-CO₂; therefore, examination of the drying conditions was not necessary. The results obtained in the present study revealed the possibility of extracting some important compounds such as hydrophobic antioxidants from waste materials with SC-CO₂. Because drying materials with high moisture levels requires costly energy, SC-CO₂ extraction can contribute to utilizing wastes or by-products with low moisture levels produced in drying processes in food and agricultural industries. If a good sweetpotato cultivar containing important enzymes or proteins together with pigments such as carotenoids is developed, SC-CO₂ extraction can serve to utilize it sequentially, i.e., to selectively extract pigments by SC-CO₂, and then use the remaining enzymes or proteins. This processing method can completely utilize sweetpotato cultivars having multiple valuable functions that are expected to be developed.
