(Received December 11, 2000; Accepted July 18, 2001)

The Dahongshan kimberlite field in Hubei Province, China, is situated in the northern margin of the Proterozoic Yangtze Craton. The kimberlites erupted in the Paleozoic (ca. 326 Ma), some of which are associated with barren lamproites. An unusually fresh garnet lherzolite collected from this kimberlite field provides an opportunity to directly study the nature of the Paleozoic lithospheric mantle beneath the Yangtze Craton. The lherzolite is moderately depleted in major element compositions (2.66wt% Al2O3, 2.82wt% CaO, and 90.9 Mg#), with a forsterite content in olivine around 90.5%. The rare earth element characteristics of the whole rock [(La/Sm)N = 13 and (Eu/Yb)N = 0.48] and of the constituent minerals such as clinopyroxene [(La/Yb)N = 61] reveal that at least two processes were recorded in the lherzolite: depletion followed by enrichment. Depletion process was derived from low degree of partial melting, as demonstrated by relatively high NiO contents (0.50%) in olivines and PPGE-enriched mantle-normalized PGE pattern of the whole rock. The enrichments in LREE and LILE are attributed to melt infiltration that must be an event prior to the kimberlite eruption as constrained by trace element and Sr-Nd isotopic data. The Rb-Sr and Sm-Nd data constrained an age of about 510 Ma, which is much older than the age of Kimberlite eruption, but consistent with the eruption time of diamond-bearing lamproites on the centre of the Craton.

The stable Gt-Opx-Cpx mineral assemblage gives a T-P estimation of 1042°C and 34 kbar, corresponding to 110 km depth, well within the graphite stability field. The geotherm inferred from this lherzolite was much higher than the typical cratonic geotherm (40 mW/m²), but still lower than the oceanic geotherm. Thus, our study and previous data demonstrate that the lithospheric mantle beneath the Yangtze craton was less depleted and was hotter in Paleozoic than the lithospheric mantle beneath typical old Cratons, i.e., the Kaapvaal, the Siberia, and the North China.

INTRODUCTION

Kimberlites occur as explosive diatremes on the old continental cratons, and the ultramafic xenoliths entrained in kimberlites usually represent samples from the upper mantle. Therefore, these xenoliths can provide important information on evolution of the continental lithospheric mantle, as previously reported for the Kaapvaal Craton, the Siberian Craton, the Wyoming Craton, the Kimberley Craton, and the Canadian Shield (Dawson, 1980; Nixon, 1987; Menzies and Hawkesworth, 1987; Griffin et al., 1984; Hoal et al., 1994; Carlson and Irving, 1994; Pearson et al., 1994, 1995). In China, a few Ordovician kimberlite pipes within the North China Craton (NCC) contain mantle xenoliths. These xenoliths are intensively altered and only a few constituent minerals are fresh enough for chemical analysis (Wang et al., 1998; Zhang et al., 2000a). In spite

*Corresponding author (e-mail: hfzhang@mail.igcas.ac.cn)
of this difficulty, garnets, chromites, and minor pyroxenes from the kimberlites and from their ultramafic xenoliths have provided valuable data on the Paleozoic geotherm and lithospheric structure of the NCC (Griffin et al., 1992; Zhou et al., 1994; Wang et al., 1998; Zhang et al., 2000a). Combined with data from the ultramafic xenoliths carried by the Cenozoic alkaline basalts, these studies manifest a lithosphere-thinning history for the NCC (Menzies et al., 1993). On the other hand, Yangtze Craton, another important craton in China, collided with the NCC in Triassic, which resulted in ultrahigh-pressure metamorphism along Dabie Mountains (Xu et al., 1992). Whether the lithospheric thinning also affected the Yangtze Craton is currently unknown, since there are virtually no data for mantle rocks from this craton. The only available mantle xenolith, a fresh garnet lherzolite, was collected from the Dahongshan kimberlite field in Hubei Province, China, which is located in the northern margin of the Yangtze Craton. This sample offers a rare opportunity to obtain the first, direct information about the lithospheric mantle beneath the Yangtze Craton. This paper presents a set of high precision geochemical and isotopic data and aims to provide some crucial insights into the mantle processes recorded in the xenolith, and further to discuss the nature and evolutionary history of the lithospheric mantle beneath the northern part of the Yangtze Craton.

Fig. 1. Simplified tectonic map showing the location of the Yangtze Craton and the distribution of diamondiferous lamproites and diamond-free kimberlites/ lamproites (modified from Ye et al. (1991) and Zhang et al. (1994)). Primary diamondiferous lamproite fields in Zhengyuan, Guizhou Province and in Ningxiang, Hunan Province are labeled as 1 and 2, respectively. The Dahongshan kimberlite/lamproite field is shown in detail and the locality of the garnet lherzolite xenolith is indicated.
**GEOLOGICAL SETTINGS AND HOST KIMBERLITE**

The Yangtze Craton is one of the three major cratons in China (Fig. 1). Its basement formed in the Neoproterozoic (1.85 to 0.85 Ga) and is covered by the Phanerozoic sedimentary rocks (Zhang et al., 1994). Three kimberlite and/or lamproite fields are known in this craton, i.e., the Dahongshan barren kimberlites in Hubei Province, the Ningxiang diamond-bearing lamproites in Hunan Province, and the Zhengyuan diamond-bearing lamproites in Guizhou Province from northeast to southwest of the Yangtze Craton (Fig. 1). The Dahongshan kimberlite field comprises about 100 small kimberlite- and lamproite-pipes or dikes, along a 70 × 30 km K-rich ultramafic rock belt extending northwestward along the Xiangfan-Guangji deep fault (Ye et al., 1991; Fig. 1). These kimberlites/lamproites intruded the Sinian-Ordovician carbonates (dolomitite) and shales (Liu and Zhao, 1991). Ten irregular kimberlite pipes or dikes outcrop near the Pengjiabang village, with the largest one covering only 0.05 km². These rocks occur as breccias made of porphyritic phlogopite kimberlite-fragments, mineral crystals, and aphanitic matrix (less than 20%). Detailed petrographic studies of the Dahongshan kimberlite field have been reported by Ye et al. (1991) and Liu and Zhao (1991). Two kimberlites from the Pengjiabang area gave very similar K-Ar whole-rock ages (326 and 327 Ma, respectively) and one lamproite from the same area gave 352 ± 7 Ma Rb-Sr mineral isochron age (phlogopite-diopside-sandine-apatite), respectively (Liu et al., 1993).

**PETROGRAPHY**

Xenoliths are rare in the Dahongshan kimberlite field. A garnet lherzolite xenolith was collected from a kimberlite pipe near the Pengjiabang village (Fig. 1). It is relatively large in size (15 cm in diameter) with dark green color and rounded shape. The lherzolite is also remarkably fresh, although olivine and some orthopyroxene minerals are completely altered to brown fibrous or radial microcrystalline aggregates of serpentines and/or chlorites in the rim (Fig. 2(a)). Garnet and clinopyroxene in the rim are almost as fresh as those in the core, and all the minerals in the core of the xenolith are very fresh with only slight alteration along grain boundaries or crystal cracks of olivine. The rock is mainly composed of Ol (60%), Opx (15%), Cpx (15%), and Gt (10%), without spinel. Accordingly, it is named as garnet lherzolite. This rock has granuloblastic texture (Figs. 2(b) and (c)), with some features of deformation and recrystallization, such as kink bands in olivine and orthopyroxene and “triple junction” between olivine and pyroxene minerals.

Most of the constituent minerals, especially olivine and orthopyroxene, are granuloblastic grains dominantly in the range of 0.1~3 mm, contrasting with the interstitial fine-grained crystals (Ol and Cpx, <0.1 mm). Granuloblastic olivines often possess small fractures filled with serpentine and magnetite. Granuloblastic orthopyroxene grains are colourless, appear as rather large crystals (1~4 mm) and show well-developed cleavages. A few orthopyroxene grains enclose olivine and clinopyroxene crystals to show poikilitic texture. Clinopyroxenes are light emerald diopside, small in grain size, and are scattered homogeneously in the rock. In contrast, garnets are relative large (dominantly in the range of 1~5 mm with the maximum up to 1 cm), red-purple in color, and generally occur as anhedral crystals. Some garnets have kelyphitic rims composed of tiny pyroxene and spinel grains that are believed to be the products of garnet decomposition at relatively low pressure. The preliminary studies demonstrated that this xenolith represents the residue after low degree partial melting of the upper mantle (Liu and Zhao, 1991).

**SAMPLE PREPARATION AND ANALYTICAL METHODS**

The xenolith was cut into several thin slices, one of which was used to make a series of 6 polished thin-sections for electron microprobe (EMP)
Fig. 2. (a): Photograph of the Dahongshan garnet lherzolite xenolith. Note that the garnet (red) and clinopyroxene (emerald) in the altered rim (white) are as fresh as those in the core. (b) and (c): Microphotographs of the lherzolite in cross-polarized light to show granular blastic and triple junction texture. Width of the field =8 mm. Ol, Opx, Cpx, and Gt represent olivine, orthopyroxene, clinopyroxene, and garnet, respectively.
analyses. The EMP data were obtained with the Cameca SX50 at the Institute of Geology and Geophysics (IGG), Chinese Academy of Sciences, and the results are presented in Table 1. The rest rock slices were trimmed to remove the altered rims and were divided into two parts. The first part was cleaned with deionized water and then powdered with agate mill to 200 mesh for major, trace elements and Sr-Nd isotopic analyses. The second part was crushed to 40–80 mesh for mineral separation. Constituent minerals (Ol, Opx, Cpx, Gt) without visible inclusions and fractures were then carefully hand-picked under a binocular microscope. The mineral separates were placed in small beakers and cleaned with acetone in ultrasonic bath for 20 minutes, rinsed with double distilled water, and then dried. Finally, the mineral separates were carefully powdered by hand with agate mortar to 200 mesh for trace elemental and isotopic analyses.

| Mg# = 100 × Mg/(Mg+Fe²⁺+Fe³⁺) atomic ratio. Data for the garnet lherzolite in this study (DHS) were derived from XRF analyses, except Cr₂O₃ and NiO which were calculated from mineral modes and mineral compositions (see Table 1). PM and GT L-W stand for primitive mantle and the average composition of garnet lherzolite from kimberlites in the world (McDonough, 1994). GT L-M is the average of 8 Cenozoic basalt-borne garnet lherzolites from the Mingxi area, Southeastern China (Liu et al., 1985; Huang et al., 1992; Qi et al., 1995).

Major oxides for the garnet lherzolite were analyzed with a Philips PW2400 sequential X-ray fluorescence (XRF) spectrometer at the University of Hong Kong (HKU). Fused glass disks were used and the analytical precision was ≤2%. The results are given in Table 2. For trace element analyses, samples (100 mg) were weighed and then dissolved in distilled HF-HNO₃ in 15 ml Savillex Teflon screw-cap capsules at 100°C for 2 days, dried and then digested with 6M HCl at 150°C for 4 days. Dissolved samples were diluted to 100 ml before analyses (for Opx and Ol, to 50 ml). A blank solution was prepared and the total procedural blanks were <50 ng for all the trace elements reported in this paper. Three duplicates of the whole rock and two standards (BEN, BHVO-1) were prepared using the same procedure to monitor the analytical reproducibility. Trace elements of these sample solutions were analyzed with a VG Elemental Plasma-Quad 3 at HKU. The discrepancy between the triplicates is less than 10% for all the elements given in Table 3. Analyses of standards are in agreement with the recommended values. The platinum group elements (PGE) and Au contents were also determined with the ICP-MS at HKU. The pre-concentration followed combination of NiS fusion and Te co-precipitation (Sun et al., 1993; Zhou, 1994). Mass 108 (¹⁰⁸Pd) and mass 105 (⁴⁰Ar⁶⁵Cu and ¹⁰⁵Pd) were determined in order to evaluate the contribution of ⁴⁰Ar⁶⁵Cu, so that ⁶⁵Cu⁴⁰Ar interference with ¹⁰³Rh can be calculated (¹⁰³Rh is the only isotope of Rh). Standard materials, WPR-1 and TDB-1, were analyzed and analytical uncertainties were better than 15% for Ru and Rh, and 10% for Ir, Pd and Pt (Zhou et al., 2000). Os data are not reported, as it is difficult to avoid the loss of Os oxides during sample preparation. The results are presented in Table 4.

For Rb-Sr and Sm-Nd isotope analyses, sample powders were spiked with mixed ⁸⁷Rb, ⁸⁸Sr and ¹⁴⁹Sm-¹⁴⁶Nd tracers and dissolved in Teflon screw-

Garnet lherzolite from the Dahongshan kimberlite

The Dahongshan garnet lherzolite xenolith possesses 44.3 wt% SiO₂, 40.9 wt% MgO, 2.82 wt% CaO and 2.66 wt% Al₂O₃. This shows that the xenolith was derived from a depleted mantle source. However, compared with the average composition of global kimberlite-borne garnet lherzolites from old cratonic lithosphere mantle (McDonough, 1994), the xenolith in this study has relatively high Al₂O₃ and CaO contents and low MgO content (Table 2), indicating a less depleted mantle source.

**RESULTS**

**Major element chemistry**

The Dahongshan garnet lherzolite xenolith...
Fig. 3. Chondrite-normalized REE diagrams for whole rock and mineral separates from the Dahongshan garnet lherzolite. Normalization values are those from Anders and Grevesse (1989). Dashed line is for the data reconstructed from the mineral modes and compositions. Note that the reconstructed REE abundances are quite consistent with the measured values, especially MREE-HREEs. (a): The Dahongshan lherzolite and its mineral separates; (b): Comparison of the Dahongshan lherzolite with its counterparts; (c): Diopside; (d): Garnet. GT L-W and GT L-M represent the average REE abundances in garnet lherzolites from worldwide kimberlites (McDonough, 1994) and from Mingxi Cenozoic basalts, respectively (Liu et al., 1985; Huang et al., 1992; Qi et al., 1995). JX-25 is a garnet lherzolite from the Jagersfontein kimberlites (Macdougall and Haggerty, 1999), which is considered to be derived from transitional zone. PHN34215 is an eclogite from the Bellsbank kimberlite (Jerde et al., 1993) and shows the exsolution of Gt and Opx within the Cpx. Global garnet-facies peridotitic diopsides and garnets are taken from Hoal et al. (1994) and Zhang (1998). Garnet rim in a polymict peridotite is from Zhang et al. (2000b).
Garnet lherzolite from the Dahongshan kimberlite

Lherzolite xenoliths are generally homogenous in major element compositions and the same minerals have uniform compositions among different grains (Table 1) except for one garnet grain in which the core shows slightly higher Cr$_2$O$_3$ and CaO contents than the rim. Olivine has Fo values of 90.5 with high NiO content around 0.49 wt%. Orthopyroxene is slightly low in Al$_2$O$_3$ (≤1.7%) and CaO (≤0.6%) contents with En values of ~91%. Clinopyroxene is Cr-diopside and slightly low in Al$_2$O$_3$, FeO, and Na$_2$O and high in MgO (Table 1). Garnet is Cr-pyrope and belongs to Group 9 according to the classification of Dawson and Stephens (1976). These garnets have MgO and Cr$_2$O$_3$ contents lower than those for the garnets from the kimberlite-borne mantle xenoliths from other cratons in the world (Nixon, 1987). A fine-grained garnet in the groundmass has higher CaO, TiO$_2$, and Na$_2$O, and lower MgO, FeO, and Al$_2$O$_3$ than the granuloblastic ones, but with about the same concentration of Cr$_2$O$_3$ (Table 1).

Trace element and PGE geochemistry

The Dahongshan garnet lherzolite xenolith clearly shows a “V”-shape Chondrite-normalized REE pattern (Figs. 3(a) and (b)), i.e., LREEs are enriched ((La/Sm)$_N$ = 13), but MREEs are depleted ((Eu/Yb)$_N$ = 0.48). This V-shape REE pattern is considerably different from the general LREE-enriched patterns ((La/Yb)$_N$ = 16.7) for the garnet peridotite xenoliths from the kimberlites on other cratons in the world (Fig. 3(b)). Diopside from this xenolith shows a strong REE fractionation ((La/Yb)$_N$ = 61), its M-HREEs are extremely depleted when compared with its global counterparts (Fig. 3(c)). In addition, the diopside mineral in this study does not show a convex-upward pattern which is common for diopsides from garnet-facies mantle peridotites in the world (Menzies et al., 1987; Qi et al., 1995; Zhang, 1998). Orthopyroxene and olivine also have LREE-enriched patterns (Fig. 3(a)), which are not supportive of a residual origin.

Garnet shows a peculiar “spoon”-shaped REE pattern (Figs. 3(a) and (d)), in remarkable contrast with the well-documented two types of REE patterns for its global counterparts: LREE-depleted or sinusoidal patterns (e.g., Hoal et al., 1994; Zhang, 1998).

The Dahongshan lherzolite xenolith and its constituent minerals (e.g., Cpx and Gt) are enriched in LILE (e.g., Ba, Rb) and depleted in HFSE (e.g., Zr, Ti) relative to the primitive mantle, showing pronounced negative Zr and Nb anomalies in the trace element spidergram (Fig. 4). Negative Ti anomaly is present in the garnet. Opx has low contents of almost all LILEs and HFSEs except for Ba and Rb that are slightly higher than the values of the primitive mantle. PGE and Ni contents in the lherzolite xenolith are very close

![Fig. 4. Primitive mantle-normalized trace element diagrams for the Dahongshan garnet lherzolite and its mineral separates. Primitive mantle values are from Sun and McDonough (1989).](image-url)
Mitchell and Keays, 1981), which is again indicative of the less depletion.

Sr-Nd isotopic compositions

The Sr and Nd isotopic compositions of the lherzolite xenolith and its mineral separates all show enriched characteristics ($\varepsilon_{\text{Sr}}$ and $\varepsilon_{\text{Nd}}$ values are 3.91 to 38.03 and $-4.40$ to $-7.19$, respectively, at the kimberlite eruption (326 Ma)) (Table 5, Fig. 6). The garnet yields identical $^{87}\text{Rb} / ^{86}\text{Sr}$ ratio to the orthopyroxene, but its $^{87}\text{Sr} / ^{86}\text{Sr}$ ratio is slightly higher than that of orthopyroxene. This could be due to a small degree of isotopic resetting for the orthopyroxene. Regression of whole rock and CPX, GT, OPX mineral separates gives a line in the Rb-Sr errorchron diagram, which corresponds to 519 Ma with a very large error ($\pm 52$ Ma) and an initial $^{87}\text{Sr} / ^{86}\text{Sr}$ ratio of 0.70412 $\pm$ 0.00006 (Fig. 7). Sm-Nd isotopic data do not define an isochron, regression of clinopyroxene, orthopyroxene and garnet mineral data gives a line corresponding to 498 $\pm$ 15 Ma with an initial $^{143}\text{Nd} / ^{144}\text{Nd}$ ratio of 0.51174 $\pm$ 0.00005 (Fig. 7).

Fig. 5. Primitive mantle-normalized PGE and related element diagram for the Dahongshan garnet lherzolite. Primitive mantle values are from Barnes et al. (1988): Ni 1950 ppm, Ir 4.4 ppb, Ru 5.6 ppb, Rh 1.6 ppb, Pt 8.3 ppb, Pd 4.4 ppb, and Au 1.4 ppb.

**Garnet lherzolite from the Dahongshan kimberlite**

**DISCUSSION**

**Mantle processes recorded in the lherzolite xenolith**

Geochemical and isotopic data suggest that the Dahongshan garnet lherzolite from the Yangtze Craton was affected by at least two mantle processes before its incorporation into the host Paleozoic kimberlite: depletion followed by an enrichment.

**Depletion process** Several aspects of the Dahongshan lherzolite xenolith indicate an early partial melting process in its mantle source. Although less depleted than the kimberlite-borne garnet lherzolite xenoliths from old cratonic lithosphere (Nixon, 1987; Jaques et al., 1990; McDonough, 1994; Zheng and Lu, 1999), the relatively high Mg (Mg# = 90.9%) and NiO (0.33wt%, Table 2) and low CaO (2.82wt%) and Al$_2$O$_3$ (2.66wt%), compared with the primitive mantle (McDonough, 1994), suggest that the Dahongshan lherzolite may represent the refractory residue after a previous melt extraction (e.g., Frey and Prinz, 1978; McDonough, 1990). This is further demonstrated by the high Fo and NiO contents in olivine minerals (Table 1).

Trace element data also support this depletion process. The lherzolite from the Dahongshan kimberlite has a V-shaped Chondrite-normalized REE pattern. The depletion in MREE ((Eu/Yb)$_N$ = 0.48; Fig. 3(b)) can be interpreted in terms of melt extraction with loss of the incompatible elements. This is also manifested by the relatively high PGE contents and the Pd/Ir fractionation (Table 4 and Fig. 5). The slight enrichment of Pd-group PGE from primitive mantle may imply a moderate depletion (Fig. 5).

There is no other report on garnet lherzolite xenoliths from the Yangtze Craton, but the counterparts exist in the Paleozoic kimberlites on the North China Craton and in the Cenozoic alkaline basalts erupted on the Cathaysia Block, Southeastern China (Fig. 1). The former rocks are seriously altered, but Al$_2$O$_3$ and CaO data still show highly depleted nature (Zheng and Lu, 1999; Lu et al., 2000). The Cenozoic basalt-borne garnet lherzolites from the Cathaysia Block (Mingxi, Fujian Province of China) have much higher Al$_2$O$_3$ and CaO contents and lower MgO than the Dahongshan garnet lherzolite (Liu et al., 1985; Huang et al., 1992; Qi et al., 1995), almost equivalent to the primitive mantle compositions (McDonough, 1994). Their REE abundances are also similar to those for the primitive mantle, but are slightly LREE-enriched (Fig. 3(b)).

**Enrichment process** The Dahongshan lherzolite xenolith shows a V-shape REE pattern, garnet separates have spoon-shape patterns and other constituent minerals, Cpx, Opx and Ol, are all LREE enriched (Fig. 3). These features indicate
an enrichment process in the mantle source, which postdated an early event of melt extraction. The V-shape REE patterns were previously reported for two reconstructed whole rock compositions based on mineral modes and mineral REE contents (Fig. 3(b)): one is a garnet lherzolite from the Jagersfontein kimberlites (Macdougall and Haggerty, 1999) and the other is an eclogite from the Bellsbank kimberlites (Jerde et al., 1993). Both were considered to have an ultra-deep origin and were interpreted as results of metasomatic enrichment.

The spoon-shape REE pattern for garnet was previously reported only for the rims of garnet from a polymict peridotite from South Africa, which was attributed to a recent metasomatism (Zhang et al., 2000b). The garnet separates from the Dahongshan lherzolite xenolith consistently show the spoon-shape REE patterns throughout the mineral. Therefore, the enrichment must be an event prior to the kimberlite eruption in the mantle. Similar REE patterns were also reported for a few clinopyroxene minerals from spinel-facies mantle peridotites (e.g., Sen et al., 1993; Zangana et al., 1997; Fan et al., 2000), which was accounted for as the result of small-volume melt infiltration into the grain (Navon and Stolper, 1987; Xu et al., 1998). High permeability of La and Ce may lead to their enrichments relative to other LREE (Pr, Nd, Sm) (Navon and Stolper, 1987). Here we tentatively consider melt infiltration in the mantle at the garnet-facies depth as the cause of the spoon-shape REE patterns for the garnet separates. Extensive melt infiltration may also account for the high LREE enrichment in clinopyroxene ((La/Yb)_N = 61; Fig. 3(c)) and its high modal proportion in the xenolith. One may question whether trapped melt/fluid inclusions exist in the constituent minerals and are responsible for the enrichment. Our petrographic study did not favor such an interpretation, because no visible melt/fluid inclusions were observed.

The enrichment in the lherzolite xenolith is further demonstrated by Sr-Nd isotopic compositions (Fig. 6). Although no isochrons were defined by our results, the Rb-Sr and Sm-Nd data show a 519 and a 498 Ma trends, respectively, both much older than the age of the host kimberlite (~326 Ma). This may imply that the enrichment event happened prior to the kimberlite eruption. The lamproites on the centre of the Yangtze Craton have a similar age of 510 Ma (Liu et al., 1993). When Sr and Nd isotopic ratios are extrapolated to 510 Ma, the xenolith whole rock and mineral separates converge at a uniform isotopic composition (ε_{Sr} = 4.06; ε_{Nd} = −4.86). This may imply that mantle enrichment event indeed happened at ~510 Ma, prior to the kimberlite eruption, and was related to the magmatic activity of the lamproites on the Yangtze Craton. These lamproites are all enriched in LREE and LILE and depleted in HFSE such as Zr (Liu et al., 1993).

**Nature of the lithospheric mantle beneath the Yangtze Craton**

The Dahongshan lherzolite xenolith shows a less depleted feature in major element composition than its counterparts from the North China Craton and other old cratons in the world (Nixon, 1987; Jaques et al., 1990; McDonough, 1994; Zheng and Lu, 1999). This may reflect modification of the Dahongshan xenolith by melt infiltration, or alternatively may indicate that the Proterozoic lithosphere beneath the Yangtze Craton chemically differs from the typical continental lithospheric mantle beneath the Archaean cratons such as the Kaapvaal, the Siberia, and the North China Craton.

Textural relationship and compositional homogeneity in mineral grains indicate that the chemical equilibrium was reached in the Dahongshan lherzolite xenolith, although the rock was infiltrated by the LREE- and LILE-rich melt. The stable Gt-Opx-Cpx mineral assemblage gives a temperature-pressure estimation of 1042°C and 34 kbar, corresponding to a depth of 110 km, for the lherzolite xenolith (Fig. 8; Bertrand and Mercier, 1986; Nickel and Green, 1985). The geotherm inferred from this result is much higher than the typical cratonic geotherm (40 mW/m²), but lower than the oceanic geotherm. This may imply that the mantle source in the region was hotter in the
Paleozoic (Zhou et al., 1994). The barren feature of the Dahongshan kimberlite indicates that the thickness of the lithosphere in the northern margin of the Yangtze Craton was less than 150 km at the time of kimberlite eruption, within the graphite stability field (Fig. 9). The presence of the diamond-bearing lamproites in the central part of the Yangtze Craton (e.g., Zhengyuan and Ningxiang) indicates that the lithosphere in these areas was more than 150 km deep (Fig. 9). The coupled trace element and Sr-Nd isotopic compositions indicate that these lamproites were originated from an enriched mantle (Liu et al., 1993). Although no more detailed study has been undertaken on these rocks, the presence of these lamproites generally requires a metasomatised phlogopite harzburgite as source materials (Mitchell and Bergman, 1991). Previous investigations on the mantle xenoliths from the old cratons revealed that the lithospheric mantle is highly heterogeneous not only horizontally but also vertically, in terms of major and trace element compositions and isotopic ratios (Nixon, 1987; Hoal et al., 1994; Carlson and Irving, 1994; Pearson et al., 1994, 1995; Wang et al., 1998). The heterogeneous nature of the lithospheric mantle and scarcity of data from the Yangtze Craton...
make its comparison with the lithosphere in other regions premature at present. However, data from this study as well as from previous studies indicate that the lithospheric mantle beneath the Yangtze Craton was possibly less depleted and was hotter in Paleozoic than the lithospheric mantle beneath the NCC.

CONCLUDING REMARKS

The mantle xenolith from the Dahongshan kimberlite is moderately depleted in major oxides such as $\text{Al}_2\text{O}_3$ and $\text{CaO}$ but considerably enriched in trace elements (e.g., LREE and LILE). This suggests that the mantle source underwent at least two different processes: melt extraction followed by enrichment. Melt infiltration was invoked as the cause of trace element enrichments. Rb-Sr and Sm-Nd isotopic data favor an interpretation that the enrichment event happened about 510 Ma ago, possibly corresponding to the lamproitic magmatic activity in the Yangtze Craton. The lithospheric mantle beneath the Yangtze Craton may be less depleted and hotter in Paleozoic than the lithospheric mantle beneath the NCC.

Acknowledgments—A Sino-British Fellowship to HFZ is gratefully acknowledged, which supported his collaborative research at the University of Hong Kong. We are also grateful to Mr. Au Dipwa, Dr. Xu P., Mrs. Liu Y., and Mr. Zhang R.-H. for technical assistance in sample preparation, electron probe, ICP-MS, and Sr-Nd isotopic analyses. This work was financially supported by Chinese National Science Foundation (49733110), Hong Kong RGC grant (HKU7110/97P), Chinese Academy of Sciences (KZCX1-07), Chinese 973 Project (G1999075504). Special thanks are given to Drs. Koshi Yamamoto, Tomoharu Miyamoto, and Cristian Dragusanu for careful review.
