Coronary Artery Responsiveness to Ergonovine Provocation in Patients Without Vasospastic Angina

A Quantitative Coronary Angiography Analysis

Kyeong Ho Yun, MD, Seoung-Nam Shin, MD, Jum Suk Ko, MD, Sang Jae Rhee, MD, Nam-Ho Kim, MD, Seok Kyu Oh, MD, and Jin-Won Jeong, MD

Summary

Even patients without vasospastic angina show vasoconstriction after intracoronary ergonovine administration. We evaluated the determinants of coronary artery responsiveness to ergonovine in such patients.

In 165 patients with no provoked electrocardiographic changes or ischemic chest pain during an intracoronary ergonovine test, total cholesterol, triglycerides (TG), high density lipoprotein cholesterol (HDL), and low density lipoprotein cholesterol (LDL) were correlated with the arterial luminal diameters before and after ergonovine infusion and after nitroglycerin injection by quantitative coronary angiography analysis.

The mean and maximal basal tone (ie, percent change between baseline luminal diameter and diameter after nitroglycerin) were 7.0 ± 9.9% and 27.9 ± 10.8%, respectively. The mean and maximal responsiveness to ergonovine (ie, percent change between minimal diameter during ergonovine infusion and diameter after nitroglycerin) were 30.3 ± 13.6% and 52.7 ± 16.0%, respectively. The TG level (r = 0.191, P = 0.016) and TG/HDL ratio (r = 0.182, P = 0.021) were positively correlated with the basal tone, whereas LDL level (r = 0.155, P = 0.048) and LDL/HDL ratio (r = 0.172, P = 0.030) were positively correlated with the responsiveness to ergonovine. By multivariate analysis, LDL level, LDL/HDL ratio, and smoking were independent predictors of more than 50% responsiveness to ergonovine.

Serum lipid profile and smoking influence the basal tone and responsiveness to ergonovine of coronary artery in patients without vasospastic angina. (Int Heart J 2011; 52: 338-342)

Key words: Ergonovine, Coronary vasospasm, Lipids

Ergonovine provocation test is used to detect coronary artery spasm in patients with suspected variant angina.1,2) The predictive accuracy of this test in patients with recurrent angina at rest and electrocardiographic changes is excellent, but even patients with atypical symptoms demonstrate a moderate nonspecific vasoconstrictive response.3) In the presence of intact vascular endothelium, ergonovine induces early and transient vasodilation followed by sustained dose-dependent vasoconstriction. However, endothelial dysfunction reduces nitric oxide activity, resulting in pronounced and sustained vasoconstriction after ergonovine administration.4,5)

Considering these findings, the coronary artery response to ergonovine may be associated with coronary risk factors causing endothelial dysfunction even in patients without vasospastic angina. The aim of the present study was to evaluate the determinants of coronary artery responsiveness to ergonovine provocation in patients without vasospastic angina by quantitative coronary angiography (QCA) analysis.

Study population: We retrospectively analyzed 165 patients with chest pain and nonsignificant coronary stenosis (< 50% diameter stenosis). Each patient was referred for definitive evaluation after presenting with atypical chest pain, defined by uncommon or no precipitating events, inconsistent location, unusual duration of pain, or inconclusive response to nitroglycerin. The exclusion criteria were cases of positive results in noninvasive tests and those of coronary intervention, previous myocardial infarction, and congestive heart failure, or documented cardiomyopathy. The study protocol was approved by the Institutional Review Board of the hospital.

After overnight fasting, blood sampling was done to measure total cholesterol, triglyceride (TG), high density lipoprotein cholesterol (HDL), low density lipoprotein cholesterol (LDL), lipoprotein (a), and high-sensitivity C-reactive protein (hsCRP) levels. Complete blood count (CBC) with a differential count was measured within 24 hours before coronary angiography. Ergonovine provocation test and angiographic analysis: All drug medications that could influence the coronary artery response to ergonovine were stopped 48 hours before testing, ex-
Coronary responsiveness to ergonovine was defined as the percent change between the MLD during ergonovine infusion and the diameter after nitroglycerin injection. Coronary artery responsiveness to ergonovine (%) = \[ \frac{\text{MLD after nitroglycerin} - \text{Baseline MLD}}{\text{Baseline MLD}} \times 100 \]

Coronary artery responsiveness to ergonovine was defined as the percent change between the MLD during ergonovine infusion and the diameter after nitroglycerin injection. Coronary responsiveness to ergonovine (%) = \[ \frac{\text{MLD after nitroglycerin} - \text{MLD after ergonovine}}{\text{MLD after ergonovine}} \times 100 \]

Small coronary arteries (< 1 mm diameter after nitroglycerin) or segments overlapped by other branches were not analyzed.

**Statistical analyses:** All measurements are represented as the mean ± standard deviation. Continuous variables were compared by t-tests, using SPSS 12.0 for Windows (SPSS Inc., Chicago, IL). Correlations between the serum lipids and the ergonovine induced changes in coronary artery diameter were analyzed using Pearson’s correlation coefficients. To perform multivariate analysis, we adopted a 50% vasoconstrictive response to ergonovine on the basis of the median value. Statistical significance was set at \( P < 0.05 \) (two-tailed).

**RESULTS**

All patients underwent the full provocation protocol, and only mild side effects not requiring premature termination of the test were observed. Seven patients experienced atypical chest discomfort, but no significant ST-segment abnormalities were observed. Normal sinus rhythm was maintained in each patient, without precipitation of heart block or significant arrhythmia. The clinical characteristics of the patients and the QCA results are presented in Table I. The mean of maximal baseline diameter stenosis of each patient by QCA was 16.9 ± 8.1%. The mean basal tone of all coronary artery segments was 7.0 ± 9.9%, and the average of the maximal value of each patient was 27.9 ± 10.8%. Mean coronary responsiveness to ergonovine was 30.3 ± 13.6%, and the average of the maximal value of each patient was 52.7 ± 16.0%. One hundred two patients exhibited more than 50% of maximal responsiveness to ergonovine (61.8%).

The mean lipid values were 190.4 ± 41.9, 154.7 ± 107.3, 50.4 ± 32.5, and 122.7 ± 35.4 mg/dL for total cholesterol, TG, HDL, and LDL, respectively. The TG level and TG/HDL ratio were positively correlated with the baseline diameter stenosis (TG: \( r = 0.206, P = 0.009 \); TG/HDL: \( r = 0.174, P = 0.028 \) and basal tone (TG: \( r = 0.191, P = 0.016 \); TG/HDL: \( r = 0.182, P = 0.021 \)) (Figure 2A). On the other hand, the LDL level and LDL/HDL ratio were significantly correlated with coronary responsiveness to ergonovine (LDL: \( r = 0.155, P = 0.048 \); LDL/HDL: \( r = 0.172, P = 0.030 \)) (Figure 2C). In the patients with more than 50% of maximal responsiveness to ergonovine, LDL level and LDL/HDL ratio were more closely correlated with coronary responsiveness to ergonovine (LDL: \( r = 0.232, P = 0.021 \); LDL/HDL: \( r = 0.219, P = 0.031 \)) (Figure 3). There was no correlation between the lipoprotein (a) and hsCRP levels and the basal tone or coronary responsiveness to ergonovine.

Values are expressed as n (%) or mean ± standard deviation. QCA indicates quantitative coronary angiography.
To evaluate the effects of other risk factors on coronary responsiveness to ergonovine, we analyzed the data according to the presence or absence of each risk factor. There were no significant differences in the basal tone between the patients with hypertension, diabetes, or smoking and those without risk factors. The coronary responsiveness to ergonovine was not influenced significantly by gender, presence of hypertension, or presence of diabetes. However, the smokers had a pronounced vasoconstrictive response to ergonovine compared to the non-smokers (36.4 ± 13.6% versus 29.1 ± 13.4%, \( P = 0.012 \)) (Figure 4). Multivariate analysis revealed that LDL level (OR = 1.07, \( P = 0.007 \)), LDL/HDL ratio (OR = 1.20, \( P = 0.022 \)), and smoking (OR = 4.14, \( P = 0.028 \)) were independent predictors of more than 50% of maximal responsiveness to ergonovine (Table II).

LDL indicates low density lipoprotein cholesterol; WBC, white blood cells; HDL, high density lipoprotein cholesterol; TG, triglycerides; and hsCRP, high-sensitivity C-reactive protein.

**Figure 4.** Coronary artery responsiveness to ergonovine in the presence (+) and absence (-) of hypertension, diabetes, and smoking. The data are the mean ± standard deviation.

**Discussion**

In this study, we have demonstrated that smoking and serum lipids could influence the basal tone and coronary responsiveness to ergonovine. In patients without significant stenosis and vasospastic angina, the TG level and TG/HDL ratio were correlated with the basal tone, and the LDL level and LDL/HDL ratio were correlated with the coronary responsiveness to ergonovine.

Coronary artery spasm plays an important role in the pathogenesis of various ischemic heart diseases, including not only variant angina but also unstable angina, myocardial infarction, and sudden cardiac death.
fraction and sudden death.\textsuperscript{8} Heupler, \textit{et al} introduced the ergonovine provocation study for the diagnosis of coronary vasospasm.\textsuperscript{9} Ergonovine provokes coronary vasospasm through a complex mechanism involving serotonin receptors, direct stimulation of \textit{α} receptors, and inhibition of nitric oxide (NO) release from the endothelium.\textsuperscript{9,20} A certain degree of nonspecific vasoconstriction can be observed in all individuals receiving ergonovine. Kimball, \textit{et al} demonstrated a progressive, dose-related reduction in coronary dimensions that was not related to the induction of chest discomfort or ECG changes.\textsuperscript{11} The clinician should not confuse this nonspecific response with true vasospastic angina. However, there is little information available about coronary “hyper-responsiveness” to ergonovine.\textsuperscript{2,15}

The mechanism of coronary vasospasm includes hypersensitivity to endothelium derived factors, platelet derived vasoactive substances, and autonomic nervous tone.\textsuperscript{14,15} The basal coronary tone is related to the regulation of vascular smooth muscle tension by local endothelium derived factors, humoral factors, and parasympathetic nervous tone.\textsuperscript{16,17} Thus, similar factors may play a role in both vasospasm and the basal coronary tone, and vascular endothelial dysfunction in particular can be a critical factor. Endothelial dysfunction leads to reduced NO activity, resulting in more pronounced and sustained vasoconstriction after ergonovine administration.\textsuperscript{4,5} Smoking reduces NO activity via oxygen radicals in cigarette smoke.\textsuperscript{18} Therefore, unsurprisingly, smoking is the only established risk factor for vasospasm.\textsuperscript{20,26} In our study, coronary responsiveness to ergonovine was the most accentuated in smokers, but not in patients with hypertension or diabetes.

Animal studies showed a relationship between experimental atherosclerosis and vasoconstriction.\textsuperscript{21-23} However, clinical studies revealed controversial results. Nobuyoshi, \textit{et al} and Harding, \textit{et al} did not find any relationship between coronary vasospasm and total cholesterol and LDL levels.\textsuperscript{24,25} On the other hand, Kugiyama, \textit{et al} have shown that oxidized LDL levels are significantly and positively correlated with the vasoconstrictive response of coronary arteries.\textsuperscript{26} Nedeljkovic, \textit{et al} reported that total cholesterol and LDL levels are significantly correlated with the baseline MLD and coronary vasoconstriction induced by ergonovine.\textsuperscript{27} We found a significant but weak relationship between the LDL level and the coronary responsiveness to ergonovine. The intersudy differences may be attributable to differences in the study populations; many studies of the relationship between the lipid profile and vasospasm included some patients with true vasospastic angina. However, we demonstrated that the LDL level may play some role in the coronary responsiveness to ergonovine even in patients without variant angina who have nonspecific vasoconstriction.

The TG level is also an important factor for atherosclerosis and endothelial dysfunction. In a hypertriglyceridemic state, the accumulation of remnants results in a proinflammatory and oxidative milieu that may enhance the expression of adhesion molecules, foam cell formation, and smooth muscle cell toxicity.\textsuperscript{28} High TG levels induce an increase in the small dense LDL level, which most easily causes atherosclerosis; and also the reduction of HDL, thereby accelerating atherosclerosis.\textsuperscript{29,30} However, there are few reports on the relationship between the TG level and variant angina so far. We demonstrated that the TG level, especially the TG/HDL ratio, is significantly related to the basal tone. Basal coronary artery tone is increased in patients with variant angiography in proportion to the disease activity.\textsuperscript{29,30} Therefore, our data suggest that the LDL level is related to the development of vasospastic angina, and the TG level is related to the disease activity of vasospastic angina.

This study has several limitations. We did not clarify the clinical significance of the basal tone and responsiveness to ergonovine in patients with chest pain syndrome and “almost-normal” coronary arteries. This study should be considered as a suggestion regarding how to identify coronary risk factors affecting the pathogenesis of coronary vasospasm. Coronary angiography frequently underestimates the atherosclerotic plaque burden in positively remodeled coronary sites; therefore, the effects of LDL and HDL levels on MLD could be underestimated in this study.

In conclusion, in patients with atypical chest pain and nonspecific vasoconstriction to ergonovine, smoking and serum lipids influence the coronary basal tone and responsiveness to ergonovine. Although the clinical significance of the coronary artery response to ergonovine in these patients has not been definitively elucidated, the clinician must control the risk factors, because they are closely related to the occurrence of coronary artery disease as well as variant angina.
