Biomarkers in Heart Failure
Yasuchika TAKEISHI, MD

SUMMARY
Appropriate use of biomarkers is clinically important for identifying heart failure in its early stage, optimizing risk stratification, and managing patients. This article describes established and traditional biomarkers as well as novel biomarkers reflective of myocardial stress, myocardial damage, extracellular matrix, oxidative stress, inflammation, renal function, micro RNAs, and heart failure with preserved left ventricular ejection fraction. This review focuses on the recent advances in cardiac and non-cardiac biomarkers of heart failure and their appropriate use in clinical practice. (Int Heart J 2014; 55: 474-481)

Key words: BNP, NT-proBNP, ST2, Troponin, H-FABP, Galectin-3, Cystatin C, Pentraxin 3

Cardiovascular diseases are the predominant cause of death in developed countries. Among the afflicted, patients with heart failure are increasing, and this complex syndrome is becoming a public health problem, especially with the aging of populations. To establish diagnostic, therapeutic, and prognostic strategies, the identification of reliable biomarkers for heart failure is necessary. Although a number of biomarkers have been developed, the ideal biomarkers should meet certain criteria: 1) non-invasive sample collection, 2) a high degree of sensitivity and specificity, 3) able to detect the disease at an early stage, 4) sensitivity high enough to reflect relevant changes in disease conditions, 5) a long half-life within the sample, 6) rapid measurement system responding to clinical needs, and 7) low cost. In this article, the focus will be on the recent advances in cardiac and non-cardiac biomarkers of heart failure and their appropriate use in clinical practice.

Myocardial Stress Markers

B-type natriuretic peptide: B-type natriuretic peptide (BNP) is a well-established biomarker, extensively used for the diagnosis and prognosis of patients with heart failure. BNP is a cardiac hormone, identified as the second compound of the natriuretic peptide family and secreted predominantly from the ventricle in response to mechanical overload. In the failing heart, increased wall stress and neurohormonal activation facilitate BNP secretion chiefly from ventricular myocytes. BNP promotes diuresis, vasodilatation, and attenuation of renin and aldosterone secretion. Tsutamoto, et al initially measured plasma levels of BNP in 85 patients with chronic heart failure and a left ventricular ejection fraction (LVEF) of less than 0.45. The plasma levels of BNP increased in proportion to the severity of heart failure. Plasma levels of BNP were 5-fold higher in non-survivors than in survivors. Among clinical and hemodynamic parameters, Cox proportional hazard analysis revealed that only plasma BNP ($P = 0.0001$) and pulmonary capillary wedge pressure ($P = 0.003$) were significant independent predictors of mortality in patients with heart failure. Plasma levels of BNP provided prognostic information independent of other variables previously associated with a poor prognosis. To date, a number of studies have reported the diagnostic and prognostic impacts of BNP in heart failure.

Beyond the prognostic value of a single BNP measurement, monitoring changes in BNP concentrations over time may be helpful for further risk stratification. Many physicians measure plasma BNP for the diagnosis, risk stratification, and monitoring of heart failure. In the Val-HeFT trial, changes in BNP over time were associated with corresponding changes in mortality and morbidity in 4,305 patients. The change from baseline to 4 and 12 months in BNP was analyzed by quartiles for subsequent mortality and the first morbid event. Baseline BNP in quartiles showed a quartile-dependent increase in mortality and the first morbid event. Importantly, patients with the greatest percentage decrease in BNP from baseline to 4 and 12 months had the lowest mortality and first morbid event whereas patients with the greatest percentage increase in BNP had the highest mortality and first morbid event. Understanding these potentials for modulation with treatment may fuel interest in serial measurements of BNP so as to guide and improve heart failure therapy.

Although BNP-guided monitoring of patients with heart failure has been reported, it is still controversial as to whether serial measurements of natriuretic peptide are useful in heart failure management. Jourdain, et al evaluated the prognostic impact of a therapeutic strategy using plasma BNP levels. A total of 220 New York Heart Association (NYHA) functional class II and III patients considered optimally treated with angiotensin-converting enzyme inhibitors, $\beta$-blockers, and diuretics were randomly assigned either to medical treatment ac-
according to current guidelines (clinical group), or to a group with the goal of decreasing plasma BNP levels to less than 100 pg/mL (BNP group). Both groups had similar baseline clinical characteristics. At the end of the first 3 months, all types of drugs were changed more frequently in the BNP group. Mean dosages of angiotensin-converting enzyme inhibitors and β-blockers were significantly higher in the BNP group (P < 0.05). Importantly, during follow-up (median 15 months), fewer patients in the BNP group reached the combined endpoint, heart failure-related death or hospital stay, than in the clinical group (24% versus 52%, P < 0.001). Similarly, in the PROTECT study, N-terminal pro-B-type natriuretic peptide (NT-proBNP)-guided patients had more frequent drug changes, and greater dose increases of therapies with improved mortality.14 On the contrary, several trials reported no difference in medical management and prognosis between the 2 arms.16,17 In addition, if the BNP-guided approach is effective even in study populations for whom the target level of BNP is not achieved, it is unclear whether BNP adds incremental value to the determination of therapy.18 It should be noted that in the Systolic Heart Failure Treatment Supported by BNP (STARS-BNP) trial, patients in the BNP-guided arm had twice the number of physician visits and more frequent medication changes than those in the standard care arm, even though only 33% reached the target BNP of less than 100 pg/mL.14

N-terminal pro-B-type natriuretic peptide: The main stimulus for proBNP synthesis and secretion from cardiomyocytes is a progressive loss of cardiomyocytes that can be detected clinically as continuously increased serum levels of troponins. Although troponin T is a sensitive and specific marker of acute coronary syndrome, Setsuta, et al27 and Sato, et al28 reported that troponin T was also detected in severe heart failure patients and associated with adverse clinical outcomes. In the Acute Decompensated Heart Failure National Registry (ADHERE), troponins were measured at the time of admission in 67,924 patients who were hospitalized for acute decompensated heart failure.29 Overall, 4,240 patients (6.2%) were positive for either troponin T or I. As shown in Figure 1, patients who were positive for troponins had higher in-hospital mortality than those who were negative for troponin (8.0% versus 2.7%, P < 0.001). The adjusted odds ratio for death in the group of patients with a positive troponin test was 2.55 (95% CI, 2.24 - 2.89; P < 0.001).

Sensitivity of troponins has expanded the clinical applications of troponin testing.30 Latina, et al have reported that troponin T is detectable in more than 90% of outpatients with stable chronic heart failure.31 With a highly sensitive assay, a dose-dependent association of troponins and risk for cardiac death has been found in these study populations at levels below the detection threshold of the standard assay. The Dallas Heart Study, a population-based study with a highly sensitive assay, demonstrated that troponin T is detectable in 25% of the general population, and that those with positive troponin T are associated with left ventricular hypertrophy, systolic dysfunction, high all-cause, and cardiovascular mortality.30

On the other hand, cardiac troponin T is detectable in the circulation of patients with non-cardiac diseases such as infection and stroke, using highly sensitive assays.31,32 Although the detailed mechanisms are still unknown, Nakamura, et al have recently reported that patients with positive cardiac troponin T are associated with high non-cardiac mortality as well as cardiovascular mortality in patients with heart failure.33

Heart type-fatty acid binding protein (H-FABP): H-FABP, a
low molecular weight (14-15 kDa) cytoplasmic and nonenzymatic protein which transports long-chain fatty acids into the cardiomyocyte, is rapidly released into the circulation from the damaged myocardium. Therefore, H-FABP has been used as an early and sensitive diagnostic marker for acute myocardial infarction. On the other hand, it has been demonstrated that the serum level of H-FABP is increased in patients with advanced heart failure, and H-FABP is a marker for myocardial cell injury and prognosis in chronic heart failure.

Niizeki, et al measured serum H-FABP and troponin T levels in 126 consecutive heart failure patients at hospital admission. They found that the positive rate of H-FABP was higher than that of troponin T in all heart failure patients (46% [58/126] versus 26% [33/126], P < 0.0001), and in severe heart failure (NYHA III/IV) patients (69% [34/49] versus 47% [23/49], P = 0.0121). The area under the receiver operating characteristic (ROC) curve was higher for H-FABP than for troponin T (0.779 versus 0.581, P = 0.009), suggesting that H-FABP had greater predictive capacity to identify high-risk patients than troponin T. However, it should be noted that serum H-FABP levels were affected by age, gender, obesity, and renal function in a large group of volunteers (n = 2,099). These effects should be taken into account in determining appropriate reference values for H-FABP.

Extracellular Matrix

Matrix metalloproteinase: Plasma levels of matrix metalloproteinase (MMP), a key determinant of extracellular matrix degradation, are increased in heart failure. The Framingham Heart Study showed that plasma MMP-9 levels were associated with increased left ventricular end-diastolic dimension and increased wall thickness, indicating that plasma MMP-9 levels may be a marker for cardiac extracellular matrix degradation and left ventricular remodeling.

Radauceanu, et al measured serum levels of amino-terminal propeptide of collagen III, MMP-1, and interleukins in 1,009 patients enrolled in the Research into Etanercept Cytokine Antagonism in Ventricular Dysfunction (RECOVER) trial. A positive correlation was detected between the 2 classes of markers (amino-terminal propeptide of collagen III to interleukin-18, TIMP-1 to interleukin-18, and MMP-1 to interleukin-10). In the adjusted multivariable model including all biomarkers, only the amino-terminal propeptide of collagen III (P = 0.03) and MMP-1 (P = 0.048) were independent predictors of the 6-minute walk test. Amino-terminal propeptide of collagen III (P = 0.001) was the only biomarker independently associated with death and hospitalization due to heart failure. These data suggest that excessive extracellular matrix turnover is associated with cardiac remodeling, functional capacity deterioration, and poor outcome in heart failure.

Galectin-3: Galectin-3, a member of a large family of β-galactoside-binding animal lectins and derived from macrophages, interacts with various ligands located at the extracellular matrix, including laminin, collagen, and integrins. Expression of galectin-3 is markedly increased in hypertrophied and failing hearts, and galectin-3 induces cardiac fibroblast proliferation, collagen deposition, and ventricular dysfunction.

Van Kimmenade, et al measured plasma levels of NT-proBNP and galectin-3 in 599 patients presenting with dyspnea at the emergency department. Levels of galectin-3 were higher in subjects with heart failure than in those without. The ROC analysis to predict 60-day mortality showed that galectin-3 had a greater AUC (0.74, P = 0.0001) than NT-proBNP (0.67, P = 0.009) as shown in Figure 2. In a multivariate logistic regression analysis, an elevated level of galectin-3 was the best independent predictor of 60-day mortality (odds ratio 10.3; P < 0.01) or the combination of death/recurrent heart failure within 60 days (odds ratio 14.3; P < 0.001).

Oxidative Stress

8-hydroxy-2′-deoxyguanosine: Oxidative stress is known to play a crucial role in the pathogenesis of heart failure. DNA in the nucleus is one of the major targets of reactive oxygen species, and 8-hydroxy-2′-deoxyguanosine (8-OHdG) is produced from deoxyguanosine in DNA by reactive oxygen species and used as a marker of oxidative DNA damage. Kobayashi, et al showed that urinary 8-OHdG was higher in heart failure patients than in control subjects, and that urinary 8-OHdG became higher as the NYHA class increased. Moreover, there was a significant correlation between urinary 8-OHdG and cardiac functional parameters.
Suzuki, et al measured serum 8-OHdG levels in 230 patients with chronic heart failure and 42 control subjects without heart failure by a sandwich ELISA. Serum 8-OHdG concentrations were higher in patients with heart failure than in control subjects ($P < 0.001$), and increased with advancing NYHA functional class ($P < 0.001$). Kaplan-Meier survival curves demonstrated that the cardiac event rate was markedly higher in patients with high 8-OHdG levels than in those with normal 8-OHdG levels (62.4% versus 29.6%, $P = 0.0007$). Serum 8-OHdG levels provide important prognostic information for the risk stratification of patients with heart failure.

**Neopterin:** Neopterin is produced by activated monocytes/macrophages upon stimulation with interferon-γ. The amounts of neopterin correlate with the capacity of activated monocytes/macrophages to release reactive oxygen species. Thus, neopterin concentrations in body fluids can be regarded as an indirect estimate of the degree of oxidative stress emerging during cell-mediated immune response.

Sasaki, et al measured the serum neopterin concentration in 198 patients with heart failure and 62 control subjects by a competitive ELISA. Serum concentration of neopterin increased with advancing NYHA functional class ($P < 0.001$). The 4th quartile of neopterin concentration was associated with the highest risk of cardiac events (11.1-fold) compared to the 1st quartile. In the multivariate Cox analysis, serum neopterin concentration was an independent risk factor for cardiac events (hazard ratio 1.70; 95% CI 1.16 - 2.50; $P = 0.0068$).

**Inflammation**

**C-reactive protein:** Activation of the inflammatory system plays an important role in the pathogenesis of heart failure. Increased plasma levels of tumor necrosis factor-α and interleukin-6 in patients with heart failure are related to decreasing functional status and provide important prognostic information for morbidity and mortality. One of the inflammatory markers, C-reactive protein (CRP), is produced in the liver in response to stimulation of various cytokines, mostly interleukin-6.

It has been reported that elevated high-sensitive CRP has an independent prognostic value in heart failure patients. Yin, et al measured serum levels of high-sensitive CRP in 108 patients with chronic heart failure and LVEF of less than 50%. In a multivariate analysis, LVEF and serum levels of high-sensitive CRP were independent significant predictors for adverse outcomes in these patients (hazard ratio, 3.714; $P = 0.024$, and hazard ratio, 2.584; $P = 0.047$, respectively). Mueller, et al evaluated the prognostic role of inflammation among 214 consecutive patients presenting with acute heart failure at the emergency department. Patients in the highest CRP tertile significantly more often required admission to the intensive care unit (33% versus 14%, $P = 0.028$) and died in hospital (15% versus 2%, $P = 0.027$) compared to the first tertile. After multivariate adjustment, CRP remained an independent predictor of death (hazard ratio, 1.4; 95% CI, 1.1 - 1.8; $P = 0.044$). Kamioka, et al examined whether high-sensitive CRP level before cardiac re-synchronization therapy (CRT) implantation was able to predict the response to CRT and cardiac deaths in severe heart failure patients. High-sensitive CRP level was significantly higher in non-responders than in responders to CRT ($P < 0.01$). Multivariate logistic regression analysis showed an independent relationship between high-sensitive CRP and the incidence of non-responders to CRT (odds ratio: 1.499, $P = 0.011$). Stepwise multivariate Cox proportional hazard analysis identified the high-sensitive CRP level as the strongest predictive factor for cardiac death (hazard ratio: 1.337, $P = 0.001$).

**Pentraxin 3:** Pentraxin 3 is a member of the long pentraxin family, and conserves the C-terminal pentraxin domain with the classical short pentraxins, but differs by an unrelated long N-terminal domain. A variety of cell types including dendritic cells, mononuclear phagocytes, macrophages, smooth muscle cells, fibroblasts, and endothelial cells can produce pentraxin 3 upon exposure to primary inflammatory signals such as interleukin-1, tumor necrosis factor-α, oxidized low-density lipoprotein, microbial moieties, and agonists for different members of the Toll-like receptor family.

Suzuki, et al measured the plasma pentraxin 3 levels in 196 patients with heart failure and 60 control subjects without heart failure by a sandwich ELISA. The cardiac event-free rate was markedly lower in patients with high pentraxin 3 levels than in those with normal pentraxin 3 levels (44.7% versus 89.2%, $P < 0.0001$). As shown in the Table, multivariate Cox proportional hazard analysis demonstrated that the plasma pentraxin 3 level (per one standard deviation increase), but not tumor necrosis factor-α, was an independent predictor of cardiac events (hazard ratio, 1.20; 95% CI, 1.03 - 1.40; $P = 0.0162$). Patients were divided into 4 groups based on plasma pentraxin 3 values from the 1st to 4th quartile. The highest 4th quartile of plasma pentraxin 3 levels was associated with the highest risk of adverse outcomes in these patients (hazard ratio, 3.714; $P = 0.024$, and hazard ratio, 2.584; $P = 0.047$, respectively).

LVEDD indicates left ventricular end-diastolic diameter; LVEF, left ventricular ejection fraction; BNP, B-type natriuretic peptide; GFR, glomerular filtration rate; hs-CRP, high-sensitive C-reactive protein; and TNF, tumor necrosis factor. (Suzuki S, et al. Am Heart J 2008; 155: 75-81.)
of cardiac events (9.23-fold compared with the 1st quartile).

Renal Function

Creatinine and estimated glomerular filtration rate: A number of studies have reported a strong association between renal dysfunction and mortality in heart failure, and the concept of cardio-renal syndrome has been widely recognized.\(^6\) Studies in patients with stable heart failure have shown that the serum creatinine level predicts mortality from progressive heart failure independently of established prognostic variables. Estimated glomerular filtration rate (GFR) from the Cockroft-Gault or Modification of Diet in Renal Disease (MDRD) equation is a strong predictor of mortality in heart failure.\(^5\) Hildege, et al reported that in 372 patients with chronic heart failure, baseline GFR was the most powerful predictor of mortality among other risk factors including NYHA functional class, the use of angiotensin-converting enzyme inhibitors, and LVEF.\(^5\) Patients in the lowest quartile of GFR values (< 44 mL/minute) had almost 3 times the risk of mortality (hazard ratio, 2.85; \(P < 0.001\)) of patients in the highest quartile (> 76 mL/minute).

Cystatin C: Cystatin C, a 13-kD basic protein, is a cysteine protease inhibitor involved in the catabolism of proteins. Cystatin C is produced in all nucleated cells at a constant rate and is freely filtered by the glomerulus without secretion or subsequent reabsorption to the blood flow.\(^4\) Therefore, cystatin C is a serum measure of renal function that appears to be independent of age, sex, and lean muscle mass.

Shlipack, et al measured serum cystatin C levels in samples collected from 4,637 participants in the Cardiovascular Health Study, a cohort study of elderly persons living in the community.\(^5\) As the levels of cystatin C increased, hazard ratio for death increased after multivariate adjustment (Figure 3). They also showed in elderly persons with heart failure that cystatin C is a stronger predictor of mortality than creatinine.\(^4\)

In the study by Arimoto, et al, Cox multivariate proportional hazard analysis revealed that the cystatin C level was the independent predictor for cardiac events (hazard ratio, 2.93; 95% CI, 1.29 - 6.64; \(P < 0.01\)), and that the cardiac event rate was markedly higher in patients with an elevated cystatin C level than in those with a normal level (44.2% versus 13.4%, \(P < 0.001\)). Furthermore, in patients with normal creatinine levels (\(n = 91\)), the cardiac event rate was similarly higher in patients with elevated cystatin C than in those with normal levels (36.4% versus 10.0%, \(P = 0.003\)).

Combination of Several Biomarkers

Myocardial stress, damage, and fibrosis: Combination of biomarkers that reflect different pathogenic aspects in heart failure would provide incremental diagnostic and prognostic value. Nizizeki, et al studied whether the combination of markers for myocardial stress and damage at admission can reliably stratify patients hospitalized for chronic heart failure.\(^4\) Circulating levels of H-FABP and BNP were measured at admission in 186 consecutive patients hospitalized for chronic heart failure. A stepwise Cox regression analysis demonstrated that high H-FABP (hazard ratio 5.416; \(P = 0.0002\)) and high BNP (hazard ratio 2.411; \(P = 0.0463\)) were independent predictors of cardiac events. High levels of both H-FABP and BNP at admission were associated with the highest incidence in cardiac mortality and cardiac events. Kaplan-Meier analysis also showed that a combination of H-FABP and BNP levels could reliably stratify patients for cardiac events.

In the HF-ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training) trial, Ahmed, et al studied whether biomarkers of myocardial stress and fibrosis improved the prediction of death in patients with chronic heart failure. NT-proBNP and galectin-3 levels were assessed at baseline in 813 patients with chronic heart failure due to left ventricular systolic dysfunction (LVEF ≤ 35%).\(^5\) Elevations of two biomarkers were associated with increased risk for both pump failure and sudden cardiac death. Clinical variables along with NT-proBNP levels were stronger predictors of pump failure (C statistic: 0.87) than sudden cardiac death (C statistic: 0.73). Addition of galectin-3 led to an improved net risk classification of 11% for sudden cardiac death, but not pump failure. Clinical predictors along with NT-proBNP levels were strong predictors of pump failure risk, with insignificant incremental contributions of galectin-3.\(^5\)

Model for End-Stage Liver Disease (MELD) score: Liver dysfunction due to heart failure is often referred to as cardiac or congestive hepatopathy. Recently, the composite Model for End-Stage Liver Disease (MELD) scoring series, with types such as MELD (including total bilirubin, creatinine, prothrombin time-international ratio (INR)) and MELD-XI (MELD excluding INR) have been developed.\(^5\) They are established scoring systems for liver or hepato-renal function, and a high score is associated with a poor prognosis, not only in patients having undergone liver transplantation, but also in those with advanced heart failure possibly requiring heart transplantation and/or a ventricular assist device.

In HF patients, MELD scoring indicates multiple organ dysfunction secondary to impaired cardiac function. Abe, et al recently analyzed 562 patients who were admitted for the treatment of decompensated heart failure.\(^5\) A MELD-XI score was graded, and patients were divided into two groups based on the median MELD-XI score. They showed that rates of cardiac death, non-cardiac death, and all-cause death were significantly higher in the high MELD-XI group than in the low MELD-XI group. In Cox proportional hazard analysis, a high MELD-XI...
score was found to be an independent predictor of cardiac death and all-cause mortality in heart failure patients. The MELD-XI scoring system, simply calculated from total bilirubin and creatinine, can identify high-risk patients having multiple organ failure associated with heart failure.66

Circulating MicroRNAs

It has been recognized that microRNAs (miRNAs) are differentially expressed in the failing heart and control a variety of cellular processes essential to the heart.67 On the other hand, miRNAs are reportedly present in the circulation and are found to be stable in plasma.68 Since their identification in the circulation, miRNAs have attracted much interest as novel biomarkers of cardiovascular diseases.69 To date, several reports have shown that circulating miRNAs demonstrate different profiles in heart failure compared to controls, and could be used as biomarkers for this syndrome.

Tijsen, et al showed that miR423-5p was specifically enriched in the blood in patients with heart failure and was related to the diagnosis and severity of heart failure.70 ROC curve analysis showed that miR423-5p distinguished patients with heart failure from control subjects with an area under the curve < 0.001. Goren, et al revealed from meticulous screening of 186 miRNAs that circulating levels of 4 prominent miRNAs (miR423-5p, miR320a, miR22, and miR92b) were increased in heart failure patients.71 There was a significant association between the miRNA-score, which was defined using the levels of these 4 miRNAs, and several important known prognostic parameters, including BNP levels, a wide QRS duration, and dilatation of the left ventricle and left atrium. However, Tutarel, et al failed to find elevations of miR423-5p levels in patients after atrial repair for transposition of the great arteries.72 Differences in study population and right ventricular overload in the study by Tutarel, et al, might be causes for this discrepancy.

Some other miRNAs were found to be linked to the diagnosis of heart failure. Corsten, et al reported that circulating levels of miR499 and miR122 were increased in acute heart failure.73 Ellis, et al investigated the diagnostic utility of miRNAs in differentiating between patients with heart failure and non-heart failure-related breathlessness.74 Four miRNAs, miR103, miR142-3p, miR30b, and miR342-3p, were differentially expressed between HF and controls, chronic obstructive pulmonary disease, and other breathless patients.

Taken together, circulating miRNAs are novel candidate biomarkers for heart failure and large-scale prospective clinical trials comparing them with known biomarkers are necessary to validate their true clinical utility.75

Biomarkers for Heart Failure With Preserved Left Ventricular Ejection Fraction

Heart failure with preserved left ventricular ejection fraction (HFpEF) comprises a growing proportion of overall heart failure. HFpEF relates to the complex interactions between ventricular diastolic dysfunction, ventricular-vascular stiffening, and comorbid illnesses such as hypertension, atrial fibrillation, diabetes, and chronic kidney disease.75 Efficient diagnostic and prognostic biomarkers remain undetermined in this population.

Biomarkers most extensively examined in HFpEF include myocardial stress and extracellular matrix biomarkers.76 Yamaguchi, et al initially reported that an elevation of BNP was a diagnostic marker of diastolic heart failure among subjects with preserved systolic function, independent of the degree of left ventricular hypertrophy.77 Myocardial fibrosis evidenced by increased extracellular matrix collagen is a key pathological feature of HFpEF, and circulating collagen markers may reflect this excess fibrosis.78 Kitahara, et al measured carboxy-terminal telopeptide of type I collagen, a marker of collagen degradation, at admission in 156 consecutive patients hospitalized for chronic heart failure.79 They found that carboxy-terminal telopeptide of type I collagen was an independent predictor of cardiac deaths and hospitalizations in HFpEF (hazard ratio, 1.210; 95% CI, 1.013-1.446; P < 0.05). Krum, et al measured plasma levels of procollagen type I amino-terminal peptide and procollagen type III amino-terminal peptide in 334 patients with HFpEF in the substudy of the Irbesartan in Heart Failure With Preserved Systolic Function (I-PRESERVE) trial.80 For each 10 μg/L increase in procollagen type I amino-terminal peptide, the hazard ratio for the primary end-point was 1.09 (95% CI, 1.052 - 1.13; P < 0.0001). For each 10 μg/L increase in procollagen type III amino-terminal peptide, the hazard ratio was 2.47 (95% CI, 0.97 - 6.33; P = 0.059). In addition, several biomarkers, including inflammation, growth differentiation factor 15, cystatin C, NT-proBNP, and galectin-3, were associated with development and clinical outcomes of HFpEF.81

Appropriate use of biomarkers is clinically important for identifying heart failure in its early stage, optimizing risk stratification, and managing patients.82 This article has described established and traditional biomarkers such as BNP, NT-pro BNP and troponins as well as novel biomarkers reflective of myocardial stress, myocardial damage, extracellular matrix, oxidative stress, inflammation, cardio-renal pathophysiology, miRNAs, and HFpEF. Since numerous novel biomarkers have been reported in the literature, a systematic approach aimed directly at identifying the clinical benefit for patients with heart failure is needed.
