Predictors of Long-Term Mortality in Patients Hospitalized in an Intensive Cardiac Care Unit
A Special Role of Anemia and Iron Status

Summary

Patients admitted to an intensive cardiac care unit (ICCU) are a heterogeneous population with a high mortality rate. The aim of our study was to investigate which clinical, biochemical, and echocardiographic parameters routinely assessed may affect long-term mortality in a non-selected ICCU population.

A total of 392 patients hospitalized between 2008-2011 (mean age, 70 ± 13.8 years, 43% women) were consecutively and prospectively assessed with the following admission diagnoses: 168 with acute coronary syndromes (ACS), 122 with acute decompensated heart failure (ADHF), and 102 with other acute cardiac disorders. Patients were treated according to the current European Society of Cardiology (ESC) guidelines.

During a mean 29.3 (± 18.9) months of observation, 152 (38.8%) patients died and 7.9% of the patients needed a red blood cell transfusion (RBC Tx). Patients who died were significantly older and had lower baseline levels of hemoglobin (Hb), serum iron concentration (SIC), total iron binding capacity (TIBC), cholesterol, and left ventricular ejection fraction (LVEF), as well as lower eGFR values, and higher white blood cell (WBC) counts and C-reactive protein (CRP) levels (P < 0.05). Predictors of death in multivariate regression analysis were age, Hb, LVEF, WBC, and CRP. The most powerful factor was hospitalization for non-ACS. The risk of long-term mortality increased with decreasing levels of Hb (P < 0.001), SIC (P = 0.001), TIBC (P = 0.009), and the need for RBC Tx (P < 0.001), as well as the diagnosis of ADHF (P < 0.001) and the absence of ACS (P = 0.007).

In ICCU patients, age, Hb, parameters of iron status, and LVEF are strong predictors of long-term mortality. Among the ICCU population, patients with ACS diagnosis have better survival. (Int Heart J 2016; 57: 67-72)

Key words: ICCU patients, Hemoglobin, Serum iron concentration, Late mortality, Risk factors

Patients admitted to an intensive cardiac care unit (ICCU) are a heterogeneous population with a common feature – an acute cardiovascular (CV) state requiring urgent lifesaving medical management. The main causes of admission are acute coronary syndromes (ACS), acute decompensated heart failure (ADHF), and other CV diseases, such as arrhythmias, conduction disturbances, pulmonary embolism (PE), cardiac tamponade, or septic shock (SS).1,2 The estimated inhospital or 30-day mortality rate among patients hospitalized in an ICCU is reported in the range 3.3 - 9.1%1,2 and increases up to 15.9% after 12 months.2 It seems to be reasonable and helpful to explore simple parameters which could act as prognostic indicators in patients with critical cardiac life-threatening conditions related to high mortality rate circumstances.

Limited and conflicting data are available on the occurrence and prognostic value of anemia in ICCU patients. Moreover, it is unclear whether anemia is an independent predictor of long-term mortality or only an indicator of bad outcome. On the other hand, it is unclear whether iron metabolism disturbances independently of hemoglobin (Hb) level influence long-term prognosis and whether there is a place for iron status and Hb concentration correction as a routine management in patients with critical cardiac diseases.

The aim of the study was to assess which clinical, biochemical, and echocardiographic parameters routinely evaluated in ICCU patients might act as indicators of poor outcome in critically ill cardiac patients. Moreover, we sought to investigate the prognostic role of anemia and impaired iron status in long-term observation in ICCU patients.

Methods

Study population: A total of 392 patients (mean age, 70 ±
13.8 years, 43% women) consecutively admitted to our ICCU between March 2008 and December 2011 were prospectively analysed. Among this ICCU population, 168 patients were admitted due to ACS (48% had ST-elevation myocardial infarction (STEMI), 38% non-ST elevation myocardial infarction (NSTEMI), and 14% unstable angina), 122 due to ADHF, and 102 with other acute cardiac disorders such as PE and SS. Among patients with acute myocardial infarction (AMI) 3.6% had 3rd Killip class (pulmonary edema) and 6% had 4th Killip class (cardiogenic shock). Among the patients with ADHF, worsening of severe valvular disease was the reason decompensation was diagnosed in 30 (16.4%). In a great majority of ADHF patients, the reason for hospitalization was clinical deterioration of previously diagnosed left ventricular dysfunction either of ischemic origin or due to cardiomyopathy. Patients were treated according to the current ESC guidelines. Vital signs and blood analysis were assessed at admission. A detailed description of the study population as well as the general methods, blood sampling, and definitions of anemia and iron deficiency (ID) were given elsewhere. Admission glyceremia, total cholesterol (TC), and low density protein (LDL) cholesterol were also included in the analysis.

The study design was compliant with the Helsinki Declaration of 1975 as revised in 1996 and it was approved by the local institutional committee on human research (Institutional rationale of 1975 as revised in 1996 and it was approved by the local population registry run by a government office. The individually responsible for the collection of individual endpoints was blinded to the Hb level. Data concerning mortality were obtained from the local population registry run by a government office.

Primary endpoint: The composite endpoint of death from any cause was evaluated during long-term follow-up. We considered all-cause mortality as a more useful parameter than major adverse cardiovascular events (MACE), because in such a heterogeneous population the majority could experience MACE in the long-term observation. The researcher who was responsible for the collection of individual endpoints was blinded to the Hb level. Data concerning mortality were obtained from the local population registry run by a government office.

Statistical analysis: The results for continuous variables (number, mean, median, standard deviation (SD), minimum, maximum) are shown in the Table. The normality of the distributions of continuous variables were evaluated using the Kolmogorov-Smirnoff normality test. Assessment of whether continuous parameters were different in the death and survival groups was conducted based on the Mann-Whitney U test for two independent groups for continuous variables not present as a normal distribution. The impact of various parameters on the incidence of death was examined using a univariate logistic regression test, while the influence of several factors was assessed using multivariate logistic regression. To assess the likelihood of death analysis, Cox proportional hazards models were calculated on the basis of per 1 year old/%/g/dL. Kaplan-Meier analysis was performed to assess differences in mortality in particular patient subgroups. The analysis was performed using the statistical software package Statistica 6.0, EpiInfo v. 6.0, accepting \( P < 0.05 \) as significant.

Results

Mean baseline Hb level was 11.8 g/dL (± 2.2), serum iron concentration (SIC) 45.0 µg/dL (± 39.2), total iron binding capacity (TIBC) 267.9 µg/dL (± 74.9), and transferrin saturation (TSAT) 17.7% (± 16.7). The table shows the baseline patient characteristics and the differences between the death and survivor groups. The prevalences of anemia and ID in the whole study population were 64% and 63%, respectively. The prevalence of anemia was comparable among females and males (67.5% versus 62.2%, \( P = 0.28 \), respectively) and higher in the ADHF group as compared to ACS patients (69.9% versus 59.4%, \( P = 0.08 \), respectively). ID and lower TIBC were more prevalent in females as compared to males (39.3% versus 25.3%, \( P = 0.02 \) and 39.1% versus 15.2%, \( P < 0.001 \), respectively).

Iron deficiency was more frequent in ACS as compared to ADHF patients (69.9% versus 62.1%, respectively, \( P = 0.19 \)). Thirty-one (7.9%) patients needed red blood cells transfusion (RBC Tx); 8 survivors (2.0%) and 23 patients who died (5.9%). The indication for RBC Tx was a decrease in the Hb level below 7.0 g/dL or hematocrit (Ht) level below 25%.

During the mean 29.3 (± 18.9) months of observation, 152 (38.8%) patients died; 58 (14.8%) in the ACS group and 88 (22.4%) in the ADHF group. Patients who died were significantly older and had a longer mean time of hospitalization as compared to survivors (Table).

Patients who died had significantly lower levels of RBC, Hb, Ht, SIC, TIBC, TSAT, TC, LDL cholesterol, and left ventricular ejection fraction (LVEF), as well as higher creatinine and lower eGFR levels (Table), while survivors had significantly lower white blood cell (WBC) and C-reactive protein (CRP) levels (Table).

Logistic regression analysis: Among the clinical, biochemical, and echocardiographic parameters, multivariate regression analysis revealed that the highest risk of death for the whole study group was found for the changes in age, Hb, LVEF, WBC, and CRP (Figure 1). Moreover, a diagnosis other than ACS was related to an increased risk of death (Figure 1). In Cox regression analysis, age and LVEF were significant predictors of death: OR 1.021 (95% CI: 1.003-1.04, \( P = 0.022 \)) and 0.98 (95% CI: 0.96-0.99, \( P = 0.029 \)), respectively.

Kaplan-Meier analysis: The risk of long-term mortality increased with decreasing levels of Hb (\( P < 0.001 \)), SIC (\( P = 0.001 \)), TIBC (\( P = 0.009 \)), and the need for RBC Tx (\( P < 0.001 \)), as well as a diagnosis of ADHF (\( P < 0.001 \)) and the absence of ACS (\( P = 0.007 \)) (Figure 2).

Discussion

Our results show an overall high mortality rate in this ICCU population (particularly consisting of ACS and ADHF patients) after long-term observation lasting almost 2.5 years. One possible explanation for the poor clinical outcome in ICCU patients might be anemia, which is a frequent condition in patients suffering from critical illness. To the best of our knowledge, this paper might be the first to have pointed out this important problem in a heterogeneous, difficult to treat ICCU population. The prevalence of anemia in patients with ACS varies from 17.5% to 28% at admission, and usually increases during hospitalization. In patients with ADHF, the incidence of low Hb level is even higher; 68% in men and 52% in women. Although anemia is a known indicator of an unfavourable clinical profile related to inferior survival in both ACS and heart failure (HF) patients, this correlation is complex.
There are multiple concomitant cardiac and extracardiac co-morbidities, which may play a key role in the induction of mild-to-moderate anemia and increase the risk of death in these patients apart from Hb level. In our study, the prevalence of anemia was higher in the ADHF group as compared to the ACS group, however, the incidence of anemia in ACS patients was much higher than reported before.\(^5,7\) Taking into consideration that hospital acquired anemia (HAA) has been reported in 18-57% of ACS patients\(^8\) as well as anemia of inflammation, so called anemia of chronic disease (ACD), in HF patients could explain these results.

Iron metabolism disturbances are common in patients with cardiac disorders,\(^12-15\) which was also confirmed in our previous study.\(^3\) Recently, increasing attention has been fo-
cused on iron deficiency anemia (IDA).\textsuperscript{12} The studies have found a high incidence of ID in chronic heart failure (CHF) patients.\textsuperscript{16} However, there are no clear data for the particular subgroups of ICCU patients. Iron deficiency in ICCU patients, as well as in those presenting with anemia, might be overlooked because assessing the parameters of iron metabolism is not always a routine practice. In our study, ID was more frequent in ACS patients than in ADHF patients. Thus, the potential cause of the higher incidence of anemia (but lower of ID) in the ADHF group could be the fact that the main cause of low Hb level might be chronic inflammation and many chronic comorbidities. On the other hand, in the ACS group the high prevalence of ID, but lower anemia, might be caused by blood loss due to invasive procedures as well as antithrombotic therapy. Patients who died, independently of basic clinical diagnosis, had lower parameters of morphology as well as iron metabolism, which was related to higher long-term mortality. A decrease in the Hb concentration of 1 g/dL resulted in a 19% increase in mortality and a 1 µg/dL decrease in SIC worsened survival by 1%. However, after adjustment of many variables routinely assessed at admission, anemia (more frequent in ADHF population), but not ID, was an independent risk factor for death. Patients who died had lower SIC and also lower TIBC (which is generally elevated in pure IDA, but usually decreased in anemia of chronic disease = ACD). In the majority of ICCU patients with many chronic comorbidities, we deal with the compound cause of anemia (IDA/ACD) with a predominance of ACD, which can explain why low TIBC was an indicator of bad prognosis.\textsuperscript{20}

The importance of iron metabolism remains valid. Some data proved a favourable effect of intravenous iron treatment on exercise capacity, functional class, and LVEF, as well as renal function and quality of life, in either anemic or non-anemic patients presenting with CHF.\textsuperscript{16-18} Moreover, other studies have shown that iron replacement therapy improves prognosis.\textsuperscript{10,19} Because anemia is highly prevalent in patients with acute cardiac states and is related to worse outcome, ICCU patients quite often require RBC transfusion (RBC Tx).\textsuperscript{20} However, this may be related to adverse events and higher mortality.\textsuperscript{21} Our results confirm this phenomenon. It is worth noting the recommendation of a restrictive strategy of RBC Tx with a cutoff in Hb level of 7 g/dL in hemodynamically stable, non-acute bleeding critically ill cardiac patients.\textsuperscript{22}

Inflammation is involved in the initiation, progression, and instability of atherosclerotic plaques.\textsuperscript{23} A recent study has demonstrated that elevated serum hs-CRP levels at admission in patients with ACS were correlated with the severity and complexity of coronary atherosclerosis, LVEF, and troponin
levels. Several studies have suggested that in addition to aggressive statin therapy, CRP modulation might be one of the treatment options to reduce CV risk. There is no doubt that in AMI patients statin therapy significantly reduces the incidence of MACE, including cardiac death. There are also trials indicating, that among AMI patients with reduced LVEF, those with elevated levels of hs-CRP are more likely to benefit from statin treatment, while those with low levels of hs-CRP do not. However, there are not enough data to recommend CRP reduction as a management target in at least HF patients. Surprisingly, our results showed that CRP as well as WBC were not the strongest predictors of long-term mortality in ICCU patients. The heterogeneity of the study population and a large proportion of patients with ADHF as well as other critical cardiac diseases might explain the lack of clinical significance of the inflammatory parameters in ICCU patients.

On the other hand, chronic kidney disease (CKD) is highly prevalent among patients with HF. Acute decompensation of HF may cause acute impairment of renal function. “Cardio-renal syndrome” is present in up to one-third of patients with HF and is related with prolonged hospitalization and worse survival. There is evidence that baseline renal insufficiency rather than worsening of renal function was associated with an increased risk of death and death or rehospitalisation among patients with decompensated HF. The negative prognostic value of CKD was also proven in patients with acute myocardial infarction undergoing percutaneous coronary intervention (PCI); the presence of CKD was related to higher mortality and higher likelihood of multivessel coronary artery disease. Moreover, in patients with CHF complicating AMI, renal dysfunction is one of the strongest discriminators of in-hospital mortality or occurrence of MACE one-month as well as one-year after discharge. Interestingly, our results show that parameters of renal function are not independent predictors of death in ICCU patients. However, it is worth noting that we analyzed only the admission values of renal function.

We also observed a trend towards increased glucose levels in patients who died, but it was not statistically significant. High admission glucose concentrations occur in patients with known or unrecognized diabetes mellitus, but also may be a result of elevated catecholamine and cortisol levels in acute life-threatening conditions. Other studies have reported the relations between admission glucose levels and long-term prognosis in diabetic patients with acute myocardial infarction and also in a general high-risk cardiac population. In our study, glyemia was assessed at admission and thus was not always fasting. This could be the reason why it was not an independent risk factor.

There is not enough data about the impact of lipid profile on survival in patients with acute cardiac diseases. However, low TC concentrations are strongly associated with increased mortality and morbidity among patients with ADHF. In our study, low TC as well as low LDL cholesterol were rather indicators of poor outcome, but not independent risk factors, which was also confirmed by other authors. In our study, hospitalization due to ADHF was related to worse prognosis as compared to ACS, which is convergent with the earlier data and might be related to well established, ESC-guided, mostly invasive treatment applied to ACS patients. Moreover, impaired systolic function, which defines HF with reduced ejection fraction (HF-rEF), correlates with a higher mortality rate. Our analysis showed that LVEF is still an important parameter in ICCU patients; even a slight decrease in LVEF resulted in a significant increase in the mortality rate and this correlation was independent of other variables in long-time observation. Surprisingly, in our study B-type natriuretic peptide (BNP), another parameter closely related to HF, was not an independent predictor of mortality. There is conflicting evidence about the predictive value of BNP/NT pro-BNP, but one of the most recent meta-analyses supports the hypothesis that natriuretic peptide-guided therapy can improve clinical outcomes in HF outpatients.

Conclusions: In ICCU patients, some of the variables routinely assessed at admission such as Hb, parameters of iron status, and LVEF are strong predictors of long-term mortality. Other variables, like parameters of inflammation and renal function together with glyemia and cholesterol concentrations, are not clinically relevant. Among ICCU patients treated according to the current ESC guidelines, those with an ACS diagnosis have better survival.
