Left Ventricular Noncompaction Combined With Epinephrine-Secreted Pheochromocytoma Inducing Heart Failure

A Case Report

Summary

Pheochromocytomas and left ventricular noncompaction (LVNC) are both rare diseases. In this patient, the long duration of the catecholamine-secreted pheochromocytoma caused myocardial ischemia, pressure overload, and hypertrophy, resulting in the onset of heart failure (HF). The LVNC might be associated with the acute attack of HF induced by the pheochromocytoma. This is the first case reporting LVNC in combination with HF secondary to pheochromocytoma. (Int Heart J 2016; 57: 254-257)

Key words: Hypertension, Myocardial remodeling, Catecholamines, Human

Pheochromocytomas are rare neuroendocrine tumours that originate in chromaffin tissue and produce their distant variant effects by secretion of catecholamines that tend to mislead physicians into making a wrong diagnosis. Although they have only about a 5% incidence of malignancy, these tumors are associated with a high risk of morbidity and mortality from cardiovascular complications. Cardiovascular complications of pheochromocytomas present as heart failure (HF), hypertension, cardiac hypertrophy, arrhythmias, or myocardial infarction, although many patients are asymptomatic and the condition may be incidentally diagnosed on imaging modalities.

In 1932, the first case of noncompaction was reported after an autopsy performed on a newborn infant with an aortic atresia/coronary-ventricular fistula. In 1984, the first isolated noncompaction cardiomyopathy was described. Left ventricular noncompaction cardiomyopathy, also known as “spongy myocardium”, is a rare abnormality of the left ventricular myocardium with two layers: a compacted layer and a noncompacted layer. LVNC was first reported in children and has recently become increasingly diagnosed in adults, which is associated with high morbidity and mortality. The clinical picture of LVNC patients ranges from no symptoms to HF, thromboembolic events, arrhythmias, and sudden death.

Making a correct diagnosis of LVNC is important as it can significantly influence decisions on long-term management and prognosis. A correct diagnosis of LVNC has important implications due to the possible association with other cardiac abnormalities, neuromuscular disorders, and/or other systemic anomalies. Here, we report an unusual case of pheochromocytoma causing LVNC with HF.

Case Report

A 28-year-old female patient presented to our Coronary Care Unit (CCU) department with “palpitations and shortness of breath for 4 days” on August 12, 2010. Paroxysmal episodes of headache were noted every 1 to 2 months for 8 years, occasionally with sweating and palpitations. No other symptoms or signs including fever, drug or alcohol abuse, or smoking were reported. Her family history was unremarkable. On physical examination, her pulse was 110 beats per minute and her blood pressure was 130/100 mmHg. Cardiovascular examination revealed an expanding left heart border and tachycardia. Mild edema of both lower limbs was seen. Few bibasilar rales were auscultated in the lungs. Her physical examination suggested biventricular heart failure. Electrocardiography (ECG) showed sinus tachycardia with ST-segment depressions by leads I, aVL, and V1-V6. Myocardial enzymes were significantly increased (Table I). Transthoracic echocardiography showed cardiac hypertrophy and dilatation, global hypokinesia with low left ventricular ejection fraction (LVEF), left atrial dilatation, and papillary muscle thickening with slight mitral regurgitation.
Myocarditis and acute left heart failure were suspected on admission.

Following HF treatment with bed rest, sodium nitroprusside and diuretics, the patient still experienced episodes of hypertension (200/120 mmHg) with palpitations, headaches, sweating, and nausea. Thoracic-abdominal computed tomography (CT) images showed a solid hypotense mass (3.7 cm × 3 cm) in the right adrenal gland with relatively well-defined borders. Given the suspicion of pheochromocytoma, 24 hour urinary excretions of total metanephrines and catecholamines were measured, which showed elevation of epinephrine in urine specimens. After treatment with the α/β-adrenergic receptor antagonist carvedilol (20 mg bid), the blood pressure was controlled (120/70 mmHg) and the symptoms of the patient were relieved. After 12 days of treatment in hospital, the serum levels of myocardial enzymes were all decreased (Table I). Two weeks later, echocardiography showed all previous symptoms had improved (Table II). However, the thickened left ventricle had a double-wall structure. In the lateral wall, the compacted layer thickness was about 5 mm, and the non-compaction layer was 16.6 mm at diastole. A number of excessively prominent trabeculations and deep intertrabecular recesses in the apical segments of the left ventricle were seen. Doppler diagnosis indicated that blood flow in the cardiac chambers was connected with recesses (Figure 1). Cardiac magnetic resonance (CMR) showed the left ventricular end diastolic diameter was 60 mm × 87 mm, left ventricular systolic and diastolic movement was weakened, and much trabecular muscle was seen inside the wall of the left ventricle (Figure 2). These results confirmed the diagnosis of LVNC. The patient was discharged from hospital with amelioration of symptoms after continued diuretic and blood pressure control.

After two months, the 28-year-old patient was re-hospitalized, and resection of the pheochromocytoma was performed. All oral drugs were ceased after the operation. Until the patient was 29 years old, she had no episodes of palpitations, dyspnea, tachycardia, or hypertension. Echocardiography was performed again at 30 years old, and the results still clearly showed a compacted layer of about 5 mm, a non-compaction layer of about 16.6 mm, ventricular trabeculations and deep intertrabecular recesses in the apex and lateral wall, and blood flow running through the recesses and cardiac chambers. However, the systolic function of the myocardium was significantly improved, and LVEF was increased to 56% (Figure 3).

### Table I. Serum Levels of Myocardial Enzymes Before and After Treatment

### Discussion

LVNC is a rare cardiomyopathy characterized by hypertrabeculation of the myocardium, and it is related to a high
incidence of death or heart transplantation. However, the diagnosis of LVNC was usually missed because its clinical picture is nonspecific. Routine transthoracic echocardiography is an excellent tool with which to diagnose LVNC. Currently, 3 non-standardized sets of criteria to diagnose LVNC by echocardiography exist. The characteristic echocardiographic findings of noncompaction are multiple, prominent myocardial trabeculations and deep intertrabecular recesses communicating with the LV cavity. Color Doppler flow imaging shows blood flow through these deep recesses in continuity with the ventricular cavity. Also, a two-layered structure between the noncompacted layer and the compacted layer is consistent with LVNC. In this case, the echocardiographic imaging showed ventricular trabeculations and deep intertrabecular recesses in the apex and lateral wall, and blood flow running through the recesses and cardiac chambers. Otherwise, the thickened left ventricle was a double-walled structure. The results of CMR also showed an abnormal structure in the myocardium. These results all confirmed the diagnosis of LVNC.

LVNC has not only a heterogeneous genetic background but also a heterogeneous pathogenetic background. The exact cause of LVNC is unknown but it is believed that myocardial ischemia or pressure overload could be responsible for the development of the deep trabeculations. In patients with LVNC, abnormal myocardial perfusion was common in both non-compacted and compacted myocardium. The defective or dysfunctional myocardial microcirculation leads to myocardial ischemia and necrosis, which caused hypertrabeculation. Another concept that may explain the pathogenesis of LVNC is that LVNC may develop secondarily by various mechanisms as an adaptive reaction of an insufficiently contracting myocardium. For example, a frustrated attempt at hypertrophying the myocardium to compensate for myocardial impairment, which in turn induces the development of LVNC. An excess of catecholamines in pheochromocytoma is usually accompanied by classical symptoms and signs, in particular paroxysmal, such as headache, sweating, palpitations, and hypertension. In some cases, severe cardiovascular complications (eg, myocardial infarction, heart failure) may occur. In the current case, all the symptoms and complications could be observed. Furthermore, all the symptoms and complications were cured and there were no relapses even if the treatment was discontinued after the pheochromocytoma resection. These suggested that the signs of the patients were mainly induced by pheochromocytoma.

Increased levels of catecholamines lead to increased oxygen consumption, vasoconstriction, cardiac afterload, increased

Figure 2. Cardiac magnetic resonance imaging showed much trabecular muscle inside the wall of the left ventricular. A: long-axis view of the heart, and B: 4-chamber view.

Figure 3. Echocardiography performed on April 12, 2012. Although the EF value increased significantly from 28% to 56%, the echocardiogram showed the compacted and non-compaction layers were similar to those observed on the August 13, 2010 echocardiogram. A: short-axis view of heart, and B: 4-chamber view.
production of reactive oxygen species, and cell hypertrophy.\textsuperscript{22)} The myocardial ischemia, pressure overload, and hypertrophy, all of which resulted in the outbreak of HF, could have contributed to the progression of LVNC. Therefore, we speculated that in this patient, the LVNC was associated with the acute attack of HF, which was induced by the pheochromocytoma-secreted catecholamines. However, it could not be confirmed that the LVNC was caused by the pheochromocytoma in this patient because the LVNC was not improved after resection of the pheochromocytoma. The association of LVNC and the pheochromocytoma should be further investigated.
