The Role of Thiol/Disulphide Homeostasis in Anthracycline Associated Cardiac Toxicity

Mustafa Topuz, MD, Omer Şen, MD, Mehmet Kaplan, MD, Oguz Akkus, MD, Ozcan Erel, PhD, and Mustafa Gur, PhD

Summary

The aim of the present study was to evaluate whether the baseline thiol/disulfide state can predict the occurrence of anthracycline induced cardiac toxicity. A total of 186 cancer patients receiving anthracycline (doxorubicin)-based chemotherapy were enrolled. All patients underwent 2-dimensional (2D) speckle tracking echocardiography (STE) to determine their left ventricular ejection fraction (LVEF) and blood samples for measuring thiol forms were obtained before treatment and 4 weeks after completion of the chemotherapy. The mean dose of doxorubicin exposure was 255 ± 39.2 mg/m². Baseline native thiol was found to be lower whereas baseline disulfide and the disulfide/total thiol ratio were found to be higher in patients who had a decrease in LVEF after anthracycline therapy. Also, the amount of decrease in LVEF was well correlated with the delta value of the thiol forms. Logistic regression analysis revealed that changes in BNP and global longitudinal strain (GLS), baseline level of native thiol, disulfide, and the disulfide/total thiol ratio were strong predictors for a decrease in LVEF.

The thiol/disulfide pathway may be a factor for predicting chemotherapy-induced cardiac toxicity as one of the oxidative stress mechanisms. (Int Heart J 2017; 58: 69-72)

Key words: Oxidative stress, Anthracyclines, Cardiomyopathy

Although chemotherapeutic treatment has led to a better prognosis for cancer patients, some treatments can increase cardiovascular morbidity because of cardiac toxicity.12 Chemotherapy-induced cardiac toxicity is complex but involves dose-related myocardial cell death and loss of myocardial mass, leading to progressive cardiac remodeling and cardiac dysfunction due to oxidative and nitrosative stress.3,4 Anthracycline, an effective chemotherapeutic agent, is a well-known example of a cardiotoxic chemotherapeutic agent.5,6 Thus, the evaluation of cardiac functions before, during, and after treatment containing anthracycline is clinically essential.

When the generation of intracellular reactive oxygen species (ROS) exceeds the local antioxidant capacity, multiple intracellular adaptive mechanisms are up-regulated to effort tissue protection and prevent progression to apoptosis and/or necrosis. One of the protective mechanisms against oxidative cell damage is the thiol groups of cellular protein.7 Thiols are a class of organic compounds that contain a sulfhydryl group (-SH) composed of a sulfur atom and a hydrogen atom attached to a carbon atom.8 Thiols (RSH) can undergo oxidation reaction via oxidants and form disulfide (RSSR) bonds.9 The formed disulfide bonds can again be reduced to thiol groups; so, dynamic thiol-disulfide homeostasis is maintained.10 This homeostasis has a critical role in antioxidant protection, detoxification, signal transduction, apoptosis, regulation of enzymatic activity, and transcription factors and cellular signaling mechanisms.11,12

Although thiol/disulfide homeostasis has been increasingly studied in many disorders, no studies thus far have investigated thiol/disulfide homeostasis in cancer patients who suffered from anthracycline-induced cardiotoxicity.13,14 Thus, we aimed to evaluate whether thiol/disulfide homeostasis may play a role in the protection of myocardial cells from anthracycline-induced toxicity as a novel oxidative stress parameter.

Methods

A total of 186 cancer patients treated with anthracycline (doxorubicin) based chemotherapy due to breast cancer (n = 120), Hodgkin’s lymphoma (n = 18), and non-Hodgkin’s lymphoma (n = 48) were enrolled. Patient demographic and baseline characteristics were recorded. Patients with systolic heart failure (LVEF ≤ 50%), coronary artery disease, acute or chronic infectious diseases, acute or chronic renal failure, chronic hepatic failure, chronic inflammatory and autoimmune diseases, treatment with angiotensin converting enzyme (ACE)/angiotensin receptor blockers (ARB) and/or β-blocker and/or statin, and concomitant dexrazoxane therapy in addition...
to anthracycline were excluded. All patients provided written informed consent and the study protocol was approved by the local ethics committee.

**Echocardiographic examination:** All conventional echocardiographic examinations were performed in the left lateral decubitus position by one cardiologist in accordance with current guidelines.\(^\text{[15]}\) The average values of all echocardiographic measurements were obtained after 3 consecutive cardiac cycles. The LVEF was calculated according to the modified Simpson’s rule.\(^\text{[16]}\) The myocardial performance index (MPI) was determined using Doppler time intervals measured from mitral inflow and left ventricular outflow Doppler tracings.

Two-dimensional (2-D) strain imaging was used to determine LV myocardial deformation before and after anthracycline therapy. For the assessment of global longitudinal, circumferential, and radial speckle-tracking strain (GLS\%, GCS\%, and GRS\%), standard 2D ultrasound images at the parasternal mid-ventricular short-axis view (at the level of the papillary muscles), the apical long-axis view, and 2-chamber and 4-chamber views were used with a frame rate between 60 and 80 fps (EpiQ 7, Affiniti 70 ultrasound system, USA) as previously described.\(^\text{[17-19]}\) After manual tracing of the endocardial borders, the software automatically traced the region of interest including the entire myocardial wall. In this process, every view of the left ventricle was divided into 6 segments. To optimize tracking, the width of the region of interest was adjusted if necessary.

The echocardiographic measurements of 30 randomly selected patients were re-evaluated by another experienced echocardiographer who was blinded to the clinical data to calculate intra and intraobserver variability on two consecutive days. Intraobserver variability was found to be 2.2% and the interobserver variability was 2.7%.

**Laboratory tests:** Serum samples were collected by a peripheral venous route before the chemotherapy and after 4 weeks. Hematologic parameters were measured from tripotassium ethylenediaminetetraacetic acid-based anticoagulated blood samples and assessed using a Sysmex K-1000 (Block Scientific, Bohemia, NY, USA) auto analyzer within 30 minutes of sampling. The serum was then separated from the cells by centrifugation at 3000 rpm/10 minutes for biochemical (Roche Diagnostics, Indianapolis, IN, USA) and thiol analyses. The serum samples for thiol were immediately stored on ice at -41°C until analyzed. Total thiol (-S-S+ -SH) consists of native and reduced thiol. First, we used sodium borohydride as a reductant solution (10 μL) to reduce disulfide bonds (-S-S-) to functional thiol groups. Similarly, after dissolving sodium chloride in 1000 mL of water–methanol solution, we obtained another reduction solution (10 μL) for determining native thiol (-SH) content. The disulfide parameter is a value which can be calculated automatically as half of the difference of the two measured values. After calculation of the main parameters (native thiol, total thiol, and disulfide numerical values) the disulfide to total thiol (Δ -S-S)/(-S-S+ -SH) ratio was obtained. The intra-assay coefficient of variation was evaluated by performing 15 repetitions in a single analytical run, using the serum of healthy subjects. The intra-assay coefficient of variation was found to be 1.5%. The inter-assay coefficient of variation was evaluated in triplicate (on 3 different dispensing cycles) in 5 different analytical runs using the serum of healthy subjects. The inter-assay coefficient of variation was 2.1%.

**Statistical analysis:** SPSS statistical software (version 16.0, SPSS, USA) was used. Variables were investigated using visual (histograms and probability plots) and analytical methods (Kolmogorov-Smirnov test) to determine whether they were normally distributed and are expressed as the mean ± standard deviation (SD) or median and interquartile range (IQR, range from the 25th to the 75th percentile). The Mann-Whitney U test was used for the comparison of two groups with a non-normal distribution of variables and the chi-square test was used to compare qualitative data for both initial and control values. Spearman correlation was performed to evaluate the association between changes in LVEF with other study parameters. Multivariate logistic regression analysis was used to identify predictors for reduced LVEF. Intraobserver and interobserver variability were measured by the coefficient of repeatability (COR).\(^\text{[20]}\) A P value < 0.05 was accepted to be statistically significant.

**RESULTS**

A total of 186 cancer patients (123 females, 63 males) with a mean age of 55.7 ± 10.8 years and who received combination anthracycline-based chemotherapy (doxorubicin, mean dose 255.2 ± 39.2 mg/m\(^2\), with cyclophosphamide in those with a diagnosis of breast cancer, and with cyclophosphamide, vincristine, and prednisone in those with a diagnosis of Hodgkin’s and non-Hodgkin’s lymphoma) were included in the present study. No clinical cardiac events were observed during the study period.

The mean LVEF was 60.6 ± 3.3%. At the end of chemotherapy, LVEF was decreased in 36 patients. We determined the criteria for a decrease in LVEF as a ≥ 5% reduction compared to its baseline value. Those subjects with a decline in LVEF (mean LVEF, 52.0 ± 5.08%) were compared to those with no change in LVEF (mean LVEF, 60.4 ± 3.03%). The baseline characteristics of the 2 groups before chemotherapy are listed in Supplemental Table I.

Patients who experienced a decline in LVEF had lower baseline native thiol (-SH) but higher baseline disulfide (-S-S-) and disulfide/total thiol (-S-S-)/(-S-S+ -SH) ratio than patients without a decrease in LVEF (Supplemental Figure 1, Supplemental Table I).

At the end of chemotherapy, native thiol was decreased, and the disulfide level and disulfide/total thiol ratio were increased in all study patients (Supplemental Table II). The change ratio (Δ) was calculated first subtracting the baseline value of the study parameters from the one month value and then divided by the baseline value. The Δ values of native thiol, disulfide, and the disulfide/total thiol ratio were more altered in patients without a change in LVEF than in those patients who had a reduction in LVEF (P < 0.001 for both Δ native thiol and Δ disulfide, and P = 0.011 for the Δ disulfide/total thiol ratio). Also, a decrease in native thiol and an increase in the disulfide level after anthracycline therapy were associated with preserved LVEF in the study patients (Supplemental Figures 2 and 3).

In TTE examination, although MPI did not show a significant change, all of the GLS, GCS, and GRS parameters had deteriorated during the early phase of the anthracycline treatment (Supplemental Table II). The intraobserver intraclass co-
Thiol homeostasis and anthracycline cardiotoxicity

To the best of our knowledge, this is the first study that showed that thiol/disulfide homeostasis may play a role in chemotherapy-induced cardiac toxicity in cancer patients treated with anthracycline based chemotherapy.

In light of previous studies that indicated the pathophysiologic role of oxidative stress in cancer, we hypothesized that there might be impaired thiol/disulfide homeostasis in cancer patients who have anthracycline-induced cardiotoxicity. Oxidative stress has attracted the interest of clinicians for a long time and it has been shown that it has a critical role in the prevention of oxidative stress in cells and its level can play a role in the development of early onset of chemotherapy-induced cardiotoxicity.

Myocardial cells, a metabolically active tissue, have an elegant system of antioxidant defenses and cell repair mechanisms against oxidative and nitrosative stress which can cause cell necrosis and/or apoptosis. The cardiotoxic mechanism of anthracycline may involve dose-related myocardial cell death, probably due to an impairment of reparatory and homeostatic mechanisms after exposure to chemotherapy. Thiol contains a sulfhydryl (-SH) group and plays a critical role in the prevention of oxidative stress in cells and its level can be altered during proliferation or apoptosis at the cellular level. As primary targets of oxygen radicals, the -SH groups of sulfur containing amino acids such as cysteine and methionine in proteins are oxidized and return to reversible disulfide bonds. The structural and functional alterations in cell proteins begin after loss of these thiol groups. Thiols to prevent the devastating effects of free radicals may reduce their plasma and tissue levels during those interactions. In fact, similar to previous studies, we found that the native thiol level was decreased whereas the disulfide level and disulfide/native thiol ratio were strong predictors for a decrease in LVEF after chemotherapy. In Supplemental Figure 3. Also, we found that patients who had higher native thiol levels at baseline seemed to be less affected by anthracycline associated cardiotoxicity. We observed significant correlations between the initial native thiol level and the disulfide level with the differences in LV global longitudinal strain. Based on our results, we believe that baseline thiol forms may be predictors of patients who in the future may suffer cardiotoxicity after anthracycline therapy.

We evaluated the LVEF with 2D STE and found significant correlations between the initial native thiol and disulfide levels with the differences in LV GLS value. Although a decrease in LVEF may reflect myocardial injury and the first sign of cardiac toxicity in cancer patients, transthoracic echocardiography or nuclear scans are not very sensitive in predicting which patient eventually develops cardiac failure. Reductions in myocardial deformation parameters in STE could be a sign of subclinical myocardial changes from cancer therapy and occur prior to any change in LVEF as assessed by conventional echocardiography. It was previously showed that GLS could be used as an early marker of chemotherapy-induced cardiotoxicity. Moreover, GLS values can also predict later reductions in EF, and is more powerful at predicting the effect of chemotherapy-induced toxicity than GL strain rate values. In our study, we also found changes in BNP levels may predict future cardiac toxicity in logistic analyses. Actually, a lot of cardiac biomarkers such as BNP, N-terminal pro-BNP (NT-proBNP), and cardiac troponin T in addition to LVEF have been studied before and showed that all of these markers may have a role in chemotherapy-induced cardiotoxicity and may be useful during the follow-up period to enable early detection.

There are several limitations with respect to measuring cardiac biomarkers levels since other diseases and conditions such as age, heart failure, or ischemia may also cause abnormal levels of BNP and troponin T.

Our study patients were similar according to baseline characteristics including age, hypertension, and diabetes mellitus which can alter plasma thiol and we also excluded patients with a history of CAD. After adjusting for all of these factors, patients with a reduced LVEF had a lower baseline level of native thiol but a higher disulfide level and disulfide/native thiol ratio than those with no change in LVEF. All of these parameters were found to be significant predictors for a decline in LVEF in logistic analyses. We can speculate that higher baseline native thiol levels could mean higher protection from oxidative stress, whereas a higher disulfide level or lower baseline thiol level could indicate a patient is more prone to the structural and functional alterations in cell proteins and apoptosis.

Conclusion: Our findings concerning thiol may provide more objective data for physicians to detect which patients are at high risk for cardiac toxicity before chemotherapy. The ability and usability of the thiol/disulfide ratio for anthracycline associated cardiotoxicity may lead to new recommendations for monitoring cancer patients during and after chemotherapy.

Limitations: Long-term follow-up of patients is needed because the full spectrum of cardiotoxicity frequently does not become apparent until months or even years after the initial cancer treatment. For this reason, patients could be followed-up for a longer period of time. Also, both other oxidative stress parameters or new biomarkers as well as imaging modalities should be studied in future trials to further validate our findings.
