Summary
A 59-year-old Japanese woman was admitted to a nearby hospital with dyspnea and general malaise. Transthoracic echocardiography revealed right ventricular (RV) dilatation with severely reduced systolic function and leftward shift of the intraventricular septum. She was initially diagnosed with acute right heart failure, and fell into cardiogenic shock requiring an intra-aortic balloon pump and inotropic agents. An endomyocardial biopsy (EMB) demonstrated extensive interstitial edema, infiltration of inflammatory cells including numerous eosinophils, and myocytolysis with eosinophil degranulation. She was histologically diagnosed with eosinophilic myocarditis. Steroid pulse therapy was initiated, and her hemodynamic status improved along with dramatic recovery of the RV function. EMB 6 days after the initiation of steroid pulse therapy showed the disappearance of infiltration and degranulation of eosinophils, although lymphocytic infiltration still remained. Positron emission tomography-computed tomography (PET/CT) 23 days after steroid pulse therapy showed an increased 18F-FDG uptake in the intraventricular septum and left ventricle, suggesting persistent myocardial inflammation. She was then treated with a maintenance dose of prednisolone. She became free of symptoms and follow-up echocardiography showed normal cardiac function 3 months after the initiation of corticosteroid treatment. In addition, EMB and PET/CT showed no inflammation. This is the first case report of fulminant and right-sided dominant eosinophilic myocarditis successfully treated with corticosteroid. (Int Heart J 2017; 58: 459-462)

Key Words: Right ventricular dysfunction, Eosinophil degranulation, Corticosteroid therapy

Myocarditis generally impairs both ventricles equally, and predominant right-sided heart failure is very rare.1 Since it was reported that the loss of right ventricular (RV) function is the most powerful predictor of death or cardiac transplantation in myocarditis,2 early diagnosis increases the chances for effective treatment. Corticosteroid therapy is recommended as the treatment for eosinophilic myocarditis, although there is limited consensus regarding the use, dose, and duration of corticosteroid therapy. Here, we report a case of fulminant right-side dominant eosinophilic myocarditis in a 59-year-old Japanese woman who was successfully treated with corticosteroid therapy.

Case Report
A 59-year-old Japanese woman visited a nearby hospital with chest discomfort. She was previously healthy, had no medical or surgical history, took no medications, and had no known drug allergies. A 12-lead electrocardiogram (ECG) showed premature ventricular contraction without ST elevation, and bisoprolol was prescribed. However, she was admitted to the same hospital with dyspnea and general malaise 10 days after the first visit. Her blood pressure was 92/49 mmHg, pulse rate was 90 bpm, and her temperature was 36.9°C. Laboratory tests showed a normal leukocyte count (7600/μL; normal value, 3400-8700/μL) with a normal absolute eosinophil count, and elevated levels of C-reactive protein (0.77 mg/dL; normal value, 0-0.3 mg/dL), troponin I (1.62 ng/mL; normal value, 0-0.04), and B-type natriuretic peptide (806 pg/mL; normal value, 0-18.4 pg/mL). ECG showed ST elevation in leads II, III, aVF, and V1 to V5 (Figure 1A). A chest X-ray showed cardiomegaly and pulmonary congestion. Transthoracic echocardiography revealed RV dilatation with severely reduced systolic function and leftward shift of the intraventricular septum. The left ventricular (LV) systolic function was also mildly reduced with an LV ejection fraction (LVEF) of about 50%. Right heart catheterization (RHC) revealed elevated right atrial pressure (RAP) and pulmonary capillary wedge pressure (PCWP) to the same extent (mean RAP: 14 mmHg and mean PCWP: 15 mmHg), and the cardiac index was 2.2 L/minute/m². Although the LV pulse pressure was preserved, that in the...
right ventricle was reduced (Figure 1B). Coronary angiography showed normal coronary arteries and an endomyocardial biopsy (EMB) was performed.

She was initially diagnosed with acute right heart failure of unknown etiology, and inotropic agents including dobutamine and dopamine were administered. She fell into cardiogenic shock and required the insertion of an intra-aortic balloon pump on the next day of hospital admission. The patient’s hemodynamic condition did not improve, and she was transferred to our hospital for intensive therapy. RV function assessed by transthoracic echocardiography deteriorated further (Figure 2A).

EMB, which was performed on admission, demonstrated extensive interstitial edema, infiltration of inflammatory cells including numerous eosinophils, and myocytolysis with eosinophil degranulation (Figures 3A and B). She was histologi-
cally diagnosed with eosinophilic myocarditis. Steroid pulse therapy (methylprednisolone, 1 g/day IV for 3 days) was initiated, and hemodynamic status improved along with dramatic recovery of the RV function within 9 days (Figure 2B) while LVEF remained unchanged. EMB 6 days after steroid pulse therapy showed disappearance of infiltration and degranulation of eosinophils, although lymphocytic infiltration still remained. Positron emission tomography-computed tomography (PET/CT) 23 days after steroid pulse therapy showed increased $^{18}$F-FDG uptake in the intraventricular septum and left ventricle (Figure 4A). She was then treated with a maintenance dose of prednisolone (0.5 mg/kg/day) with gradual tapering to 5 mg/
day over 3 months. She became free of symptoms, and follow-up echocardiography and RHC 3 months after the initiation of corticosteroid treatment showed normal cardiac function and normal intra-cardiac pressures (Figure 1C). PET/CT showed no abnormal $^{18}$F-FDG uptake (Figure 4B) and EMB revealed small replacement fibrosis but no inflammatory cells (Figures 3C and D).

Sero-ology testing during admission revealed no signs, symptoms, or objective evidence of specific causes of eosinophilic myocarditis such as parasitic infection, drug hypersensitivity, or vasculitis associated anti-neutrophil cytoplasmic antibody. However, there were increases in anti-Coxsackie B4 and Herpes simplex viral titers. On the other hand, she was also diagnosed with Sjögren’s syndrome, which was confirmed by positive results for SS-A/Ro antibodies, Schirmer’s test, and lip biopsies.

**Discussion**

This is the first case report of fulminant and right-sided dominant eosinophilic myocarditis successfully treated with corticosteroid. The present case showed RV dilatation with severely reduced systolic function and leftward shift of the intraventricular septum on echocardiography. In addition, right heart catheterization revealed elevated right atrial pressure and reduced RV pulse pressure, which were consistent with right-sided heart failure. The patient also had elevated PCWP with pulmonary congestion at presentation. In the setting of acute right heart failure, the heart becomes constrained by the inelastic pericardium secondary to rapid increases in RV and right atrial volume, and which can produce approximate equalization of right atrial, pulmonary venous, and ventricular diastolic pressures. Although the present case did not undergo invasive intra-pericardial pressure measurement, it can be helpful to distinguish pericardial constraint from other causes of elevated PCWP and pulmonary congestion. In the present case, the LV failure may partially contribute to the PCWP elevation because LVEF mildly decreased from the onset of heart failure and FDG-PET/CT showed abnormal $^{18}$F-FDG uptake in the intraventricular septum and left ventricle even after steroid pulse therapy. The patient was successfully diagnosed with eosinophilic myocarditis by initial EMB, which showed eosinophilic degranulation. Although there is limited consensus regarding the use, dose, and duration of corticosteroid therapy in eosinophilic myocarditis, the refractory RV dysfunction dramatically recovered after corticosteroid therapy. In addition, FDG-PET/CT 23 days after the initiation of steroid pulse therapy showed no uptake of $^{18}$F-FDG in the RV free wall, suggesting marked regression of myocardial inflammation in the right ventricle. The etiology of the eosinophilic myocarditis remained unidentified in the present case. Although the patient was diagnosed with Sjögren’s syndrome during hospitalization, autoimmune myocarditis is rarely complicated with this disease, and the incidence of eosinophilic myocarditis has never been reported. In addition, increases in two elevated viral titers were found, which made it impossible to distinguish between viral and non-viral etiologies.
