Summary
Here, we report on a healthy 30-year-old man with no significant medical history, who tested negative for human immunodeficiency virus antigenemia but developed Aspergillus pancarditis. A case of this kind is extremely rare, and to the best of our knowledge, this is the first report of a patient with Aspergillus pancarditis, which generally leads to a very poor outcome, who had a long-term favorable clinical course. A biopsy from the right atrium of hypertrophied atrial septum was essential for obtaining the definitive diagnosis. Long-term administration of an effective antifungal oral agent might account for the patient’s favorable outcome.

Key words: Pancarditis, Biopsy

Aspergillus species infections can be severe and invasive, involving almost every major organ system. Aspergillus pancarditis is especially rare, with a very poor prognosis. Our patient with Aspergillus pancarditis had a long-term favorable course, which might be accounted for by the following important factors: a definitive diagnosis by a biopsy from the right atrium, early administration of an antifungal agent, timely changing to a more effective agent, and continuation of treatment based on serum β-d-glucan levels. This report should provide helpful information for the treatment of similar cases.

Case Report
We report a 30-year-old male patient with no significant medical, family, or occupational history, who had never used any intravenous drugs. The chief complaints of high fever and cough appeared in the latter third of March 2013; he was admitted to another hospital in April of the same year and received antibiotic therapy. However, his fever of 38°C and cough persisted, and he was admitted to our hospital for specialized workup and treatment.

Malignant lymphoma or infective endocarditis was suspected at the time of his admission, based on test results indicating inflammation (C-reactive protein = 4.2 mg/mL, reference range < 0.3 mg/mL), chest computed tomography (CT) imaging showing pericardial effusion without findings suggestive of pulmonary aspergillosis, echocardiogram showing vegetations (Figure 1A and B), and gallium scintigraphy scan showing abnormal accumulation of gallium within the pericardial space. However, because of an abnormally high serum β-d-glucan level (612 pg/mL, reference range < 20 pg/mL), which suggested fungal infection, we started an intravenous antifungal agent (voriconazole 400 mg/day). Transesophageal echocardiography showed extensive thickening of both atrial walls, focused around the mitral annular ring, and including the atrial septum (Figure 2). Moreover, malignant lymphoma was suspected because of the large pericardial effusion, and pericardiocentesis was performed. Approximately 800 mL of yellow to faintly bloody pericardial fluid was obtained. The cytological diagnosis was negative for malignancy; therefore, we performed a myocardial biopsy. Under intracardiac ultrasound guidance, we obtained a sample of the hypertrophied atrial septum from the right atrium, near the oval window. The histopathological findings included scattered macrophages, lymphocytes, and eosinophils. Elongated figures scattered among the cells appeared to be fungal filaments (Figure 3A). Grocott staining revealed the same filamentous structures (Figure 3B), and blood tests were positive for the Aspergillus antigen (2.8 ng/mL, reference range < 0.5 ng/mL). Aspergillus pancarditis (endocarditis, myocarditis, and pericarditis) was diagnosed, and the antifungal agent was continued. However, because the abnormally elevated serum β-d-glucan levels persisted (1180 pg/mL), the patient’s treatment was changed on day 37 from voriconazole 400 mg/day to amphotericin B 150 mg/day. Beginning around day 50, the β-d-glucan level started to decrease. Echocardiography findings indicated improvement of the mural hypertrophy by day 50, and the mobile, vegetation-like shadow attached to the mitral annular ring...
had also disappeared. Three months after admission, hy-
pertrophy affecting the base of the aorta; the walls of both 
atria, including the atrial septum; and the base of the pos-
terior atrial wall had further improved to almost normal 
(Figure 1C and D). Furthermore, the pericardial effusion
did not return after pericardiocentesis.

The electrocardiogram showed atrial flutter with 5:1 
conduction and a heart rate (HR) of 40 beats per minute 
(bpm) from the time of admission (Figure 4A) and junc-
tional rhythm (HR = 48 bpm) from day 50 (Figure 4B). 
Three months after admission, the patient’s sinus rhythm 
returned (HR = 70 bpm; Figure 4C).

Renal dysfunction manifesting as a high serum cre-
atinine level (1.5 mg/dL, reference range <1.0 mg/dL) was 
observed from around day 60, and because nephrotoxicity 
is associated with amphotericin B, the patient’s therapy 
was changed to oral voriconazole 400 mg/day. The pa-
tient’s renal function did not deteriorate further, and his 
serum creatinine level decreased to 1.2 mg/dL.

Other laboratory data, including complete blood 
count, parameters of liver and renal function, and cre-
atinine kinase levels, did not change markedly over the 
course of treatment. The changes in test values during the 
patient’s hospitalization are as follows: white blood cell 
counts = 4.9-8.6 × 10^3/μL (reference range: 4.0-9.0 × 10^3/ 
μL), hemoglobin levels = 12.6-15.2 g/dL (reference range: 
12.0-18.0 g/dL), platelet counts = 17.2-24.8 × 10^4/μL (ref-
rence range: 17.0-42.0 × 10^4/μL), glutamic-oxaloacetic 
transaminase levels = 21-40 U/L (reference range: 0-44 U/ 
L), glutamic-pyruvic transaminase levels = 13-27 U/L 
(reference range: 0-47 U/L), creatinine kinase levels = 56-
Figure 3. Pathology findings. A: HE stain × 1,000. Scattered macrophages, lymphocytes, eosinophils. Elongated shapes between the cells appear to be fungal filaments (yellow arrows). B: Grocott stain × 1,000. The filaments are short, friable, and swollen, suggestive of filamentous fungi (yellow arrows).

Figure 4. ECG changes. A: admission, B: day 50, C: 3 months after admission.

65 U/L (reference range: 57-174 U/L), creatinine kinase-MB isozyme levels = 3.2-3.4 U/L (reference range: 0-12 U/L). The patient’s body temperature improved to 36.5°C at day 10 after admission and remained below 37°C.

Although the patient was restarted on oral voriconazole at around day 60 because of amphotericin B-associated nephrotoxicity, his Aspergillus-related symptoms were not exacerbated, and his β-d-glucan values decreased to 144 pg/mL. Subsequent Aspergillus antigen testing was negative, and the patient was discharged on day 148 with a prescription for ongoing oral voriconazole.

Discussion

Aspergillus infection usually affects the lungs, with rapid hematogenous dissemination to all organs and formation of microabscesses.1 When Aspergillus infects the heart, it causes an acute pathological state, including endocarditis, myocarditis, and pericarditis.2 Symptoms progress insidiously and rapidly during myocarditis, and patients commonly die within a few hours to a few days.3-4 We believe that the favorable clinical outcome of our patient was accounted for by the patient’s normal left ventricular function, the absence of an underlying disease that would cause impaired immunity, and the effectiveness of the antifungal agent against our patient’s infection. Furthermore, the finding that creatinine kinase levels, including creatinine kinase-MB isozyme, were within the normal range, suggesting that the patient’s Aspergillus infection might have been localized to the atria and conduction system; the localized infection might have been one of the most important factors leading to the patient’s favorable outcome.

Identifying the route of infection was a challenge in this case. Usually the pathogen reaches the lungs through inhalation; however, there was no lesion suggesting respiratory infection on the CT images of our patient. There was no history of penetrating trauma. There are various routes of infection, but usually Aspergillus does not spread hematogenously unless the patient has impaired immunity. Our patient was a healthy young man with no significant medical history, who was negative for human immunodeficiency virus antigenemia.

The definitive diagnosis of Aspergillus infection by standard sputum cultures is difficult, and tissue biopsy is usually required. This invasive test provides the correct diagnosis in 10%-30% of cases. The blood culture positivity rate is extremely low, at 6.4%-11%.5 Aspergillus was not
isolated from our patient’s blood or pericardial fluid cultures but was histopathologically identified from myocardial tissue. The biopsy sample from the right atrium of hypertrophied atrial septum was essential for obtaining the definitive diagnosis in our patient.

Treatment for *Aspergillus* carditis is based on antifungal agents such as amphotericin B. However, systemic infection usually occurs during the time of diagnosis, and because the infection rapidly progresses, the prognosis is extremely poor. However, this case represents a favorable clinical course; more than 2 years have elapsed since the patient’s treatment was changed to oral voriconazole. Data on the duration of oral antifungal administration during maintenance therapy are scarce, and to date, we have continued administration of voriconazole. This case is important, because to the best of our knowledge, this is the first report of *Aspergillus* pancarditis with a long-term favorable clinical course. Going forward, we will also need to consider the risk of reactivation of infection, and whether or not diligent follow-up observations, including echocardiography, ECG, and sample collection and testing are needed.
