SUMMARY

Many factors may affect the interventricular septal motion. This study measures the effect of pericardiectomy on septal motion in 9 patients who were evaluated 1 week to 58 months after pericardiectomy. Echocardiography was performed with the patient in recumbent position with the special care to record motion of the muscular septum and not that of the aorta. No patient had left bundle branch block, angina, myocardial infarction, pericardial effusion or right ventricular volume overload. Septal motion was paradoxical in 7, normal in 1 and could not be evaluated in 1 patient. The mean value of the right ventricular internal dimension was normal. Two of 9 patients had technically satisfactory echocardiograms preoperatively. Septal motion was normal in both, and both developed paradoxical septal motion postoperatively. We conclude that paradoxical septal motion follows pericardiectomy, but in contrast with other causes of this finding right ventricular internal dimension remains normal.

Paradoxical septal motion  Differential diagnosis

ECHOCARDIOGRAPHIC significance of combined abnormal septal motion and increased right ventricular internal dimension in the diagnosis of right ventricular volume overload has been established.\(^1\)-\(^7\) Abnormal septal motion has also been described in left bundle branch block,\(^8\),\(^9\) coronary artery disease,\(^10\) following aortic valve replacement,\(^10\) in Wolff-Parkinson-White syndrome\(^11\) and in the majority of individuals who have undergone successful closure of an atrial septal defect.\(^6\)

This retrospective study was undertaken to determine the echocardo-
graphic features of pericardiectomy and its effect on the motion of the ventricular septum which was partly similar to that observed in right ventricular volume overload.

**Patients and Methods**

A total of 9 patients were evaluated 7 days to 58 months (mean, 24 months) after pericardiectomy. There were 4 women and 5 men with ages ranging from 20 to 63 years (mean, 46 years). Six patients had constrictive pericarditis presumed tuberculous, and 3 patients had recurrent (probably viral) pericarditis. Pericardiectomy was carried out through a left anterolateral thoracotomy, with removal of pericardium and its adhesions from phrenic nerve to phrenic nerve.

Echocardiography was performed using an Ekoline-20 ultrasonoscope, a 2.25 MHz transducer of 7.5 cm focal length, 1.3 cm in diameter, and an Irex strip chart recorder. With the patient in a recumbent position, scanning of the heart was carried out by placing the transducer at the fourth intercostal space and aim-
ing the ultrasonic beam from the aortic root to the apex of the left ventricle. Special care was taken to record motion of the muscular septum and to avoid the membranous septum close to the aorta whereby a falsely abnormal motion is not uncommon (Fig. 1). Paradoxical septal motion (type A) was defined as right and left sides of the interventricular septum moving anteriorly during ventricular systole. Right and left ventricular internal dimensions and interventricular septal thickness were measured at end-diastole.

**Results**

Clinical improvement was noted in all patients postoperatively. All but 2 were in sinus rhythm. One individual had trivial aortic incompetence. No patient had left bundle branch block, fascicular block, or myocardial infarction.

Paradoxical septal motion (type A) was observed in 7 patients, normal motion of the septum in 1, and it could not be evaluated in 1 patient (Fig. 2).

![Fig. 2. Postoperative echocardiogram of the same patient, exhibiting paradoxical septal motion. In contrast with the previous figure, the septum begins to move anteriorly following the R wave and reaches its maximum anterior position at the end of systole. Note that the excursion of the left ventricular posterior wall is exaggerated. IVS: interventricular septum.](image-url)
Right ventricular internal dimension ranged from 1.3 cm to 2.2 cm in 8 patients, with the mean of 1.82 cm. Interventricular septal thickness ranged from 0.6 to 1.25 cm (mean = 0.98 cm). The ratio, right ventricular dimension/left ventricular dimension had a mean value of 0.27 (range: 0.22-0.37) in 4 patients with paradoxical septal motion in whom left ventricular dimensions could be measured. Three patients had preoperative echograms. Septal motion was normal in 2 and could not be evaluated in 1. Septal motion changed from normal to paradoxical in the 2 patients with legible preoperative echocardiograms.

**DISCUSSION**

Although the exact mechanism of production of abnormal septal motion observed in several disorders remains obscure, some tentative explanations have been offered. In patients with left bundle branch block the abnormal septal motion has been attributed to the disordered electrical activation. In individuals with right ventricular volume overload, the disparity between right and left ventricular volumes has been offered as a plausible explanation for abnormal septal motion. Tajik et al have attributed the septal motion abnormalities to the magnitude of left to right shunt. Meyer et al relate the abnormal septal motion to the net anterior systolic motion of the entire heart in the presence of severe right ventricular dilatation. Laurenceau and Dumesnil have explained abnormal septal motion on the basis of right ventricular enlargement and have suggested that all patients with right ventricular to left ventricular ratio greater than 0.6 have this abnormality. This ratio was 0.37 in the 4 of our patients in whom it was measurable.

In many instances, however, paradoxical septal motion is observed in the absence of right ventricular volume overload, conduction disturbances of myocardial infarction, and no satisfactory explanation has been offered for these. Kerber et al have observed persistence of abnormal septal motion in the majority of patients who have undergone successful closure of an atrial septal defect. We have commonly observed abnormal septal motion after aortic valve replacement, mitral valve replacement, open mitral commissurotomy and up to 11 years after repair of atrial septal defects. However, we have not observed abnormal septal motion following closed mitral commissurotomy.

An explanation for abnormal septal motion in patients after pericardectomy and in many individuals after heart surgery may lie in the anatomical and functional contribution of an intact pericardium to normal septal motion.
The restrictive function of the pericardium on the heart has been previously documented both in animals and man.\textsuperscript{13} This important function no longer exists in pericardiectomized patients and many who have had pericardiectomies. Under these circumstances, it is possible that the entire heart moves forward in systole, thereby systolic posterior movement of the septum is counterbalanced by a greater anterior motion, resulting in a net anterior septal motion. A similar observation has been made by Payvandi et al\textsuperscript{14}, who found paradoxical septal motion in pericardiectomized individuals and in patients with congenital absence of the pericardium. This hypothesis would also explain the abnormal septal motion in patients who have undergone open cardiac surgery and in whom the pericardium has either been left open or closed loosely with the loss of its functional integrity. Retention of normal septal motion observed in patients after closed mitral commissurotomy can easily be explained since the pericardium is not widely opened in these patients, and is closed securely after commissurotomy.
