Left Atrial Myxoma
An Ultrastructural Study

P. CHOPRA, M.D. and V.K. SHARMA, M.D., D.C.P.

SUMMARY
Electron microscopic observations of 4 excised cardiac myxomas were made. All were present in the left atrium and all but one had a stalk. The hearts were otherwise normal. Several types of mesenchymal cells in varying stages of differentiation were identified. Cells having some features of smooth muscle, fibroblasts, and endothelium were observed. Some cells having features of both smooth muscle and fibroblasts namely, myofibroblasts were also encountered. Macrophages, lymphocytes and plasma cells were also seen in small numbers. Hematopoietic foci and calcification were not seen in any of our cases. Ultrastructurally, fine electron dense granules and only stray collagen fibres were noted in the matrix.

Myxomas possibly represent either hyperplasia or a true neoplasm of the subendocardial multipotential cells that are capable of differentiating into various types of mesenchymal elements.

Additional Indexing Words:
Cardiac myxoma  Multipotential mesenchymal cells  Hyperplasia  Myofibroblast

HISTOGENESIS of cardiac myxomas has been a subject of much debate. The two controversial views are whether these are thrombi or neoplasms. Several reports based on light microscopy, histochemistry, and ultrastructural studies favour their neoplastic nature. Salyer and coworkers, however, have postulated the thrombogenic nature of myxomas. In an earlier report we have described the gross, light microscopic and histochemical features of cardiac myxomas. Since then an additional case has been subjected to surgery. This communication is based on a detailed electron microscopic evaluation of 4 cases in an attempt to define the histogenesis of this entity.
MATERIALS AND METHODS

Eight cardiac myxomas were surgically excised between the years 1976 and 1981. Four cases were subjected to electron microscopy. Small pieces of the excised lesion were taken from multiple sites and cut into 1 mm³ segments and processed. After fixation for 2 hours in 1% osmium tetroxide in veronal buffer, the pieces were dehydrated through ascending grades of alcohol and embedded in Epon. Sections were cut on a Reichert ultratome, after which they were stained with uranyl acetate and lead hydroxide and examined under a Philips 300 electron microscope operated at 60-80 kv. Thick sections (1μ) from each block were stained with 0.2% toluidine blue and examined under the light microscope in order to select the area for electron microscopic examination.

Small pieces of myxomas were also fixed in 10% buffered formalin and processed conventionally for light microscopy. Five μ thick paraffin sections were stained with hematoxylin and eosin. On selected sections from all cases, phosphotungstic acid hematoxylin (PTAH), Masson Trichrome, Verhoff’s Van Gieson (VVG), Wilder’s reticulin, alcian blue, periodic acid shiff (PAS), iron and toluidine blue stains were also used.

RESULTS

Patients ranged in age from 13 to 48 years. There were 5 males and 3 females. All the masses were located in the left atrium in the region of the fossa ovalis. Patients were NYHA functional class I to class IV and the duration of their complaints ranged from 6 to 36 months (Table I).

All the excised growths were lobulated, greyish pink and gelatinous, varying in dimensions from 4.5×3.5×1.5 cm to 8×5×2 cm, with the weight varying from 19 to 25 Gm. All but one had a stalk which varied in thickness and length from 0.5 cm to 2×1.5×0.2 cm. The cut surface was smooth or bosselated and was variegated red, grey and yellow. All the lesions were soft and mucoid.

Light microscopy revealed essentially similar features in all the myxomas. The cells were round or polygonal, arranged singly, in small groups, in syncytium, or in a gland-like manner around thin walled vascular channels in scant to abundant mucopolysaccharide rich stroma. Hemosiderin laden macrophages, a few plasma cells and lymphocytes were also encountered. No hematopoietic foci or calcification was observed in any of the cases.

Electron microscopic observations

Findings were more or less identical in all 4 cases. Cellularity was

sparse and the cells were dispersed in an abundant stroma composed of fine electron dense granules and occasional collagen fibres. The cells were present either singly or in small groups varying from 3–7 in number that were closely apposed (Figs. 1, 2). The cells were round to ovoid and polyhedral with irregular outlines. Most of the cells had prominent villous projections of the cell membrane with some interdigitations with the neighbouring cells (Figs. 1–3). Intercellular contact between cells that occurred in groups consisted of areas in close apposition to the plasma membrane of adjacent cells. These regions, that is, the zonulac adherentes constituted only a small fraction of the
total area of contact (Fig. 2). Nuclei were round to ovoid and in some cells even elongated (Figs. 1, 2, 5). The nuclear membranes at times showed deep indentations (Fig. 2). Nuclear chromatin varied considerably in amount and distribution and was moistly seen to be condensed along the inner nuclear membrane (Figs. 1, 2). Nucleoli were prominent (Fig. 2). Cells that contained only a few organelles had large nuclei whereas those that had moderate to abundant cytoplasmic organelles, had small, round to ovoid somewhat eccentric nuclei.

Electron microscopic features resembling smooth muscle cells, fibroblasts and endothelial cells were observed. Myofibroblasts, i.e., cells having features of both muscle cells and fibroblasts, were also identified. The following cell types were encountered and are described below according to the type and distribution of cytoplasmic organelles.

1. This cell type was most frequently encountered. The cellular membrane was thrown into prominent folds (Fig. 1). Cytoplasmic organelles were few and unevenly distributed. The most striking features in these cells were the numerous microfilaments present in parallel bundles which crisscrossed in various directions (Fig. 1). These were seen around the nucleus and in between organelles thus pushing the latter towards the periphery. These filaments lacked periodicity and resembled myofilaments. At places the filaments were condensed along their course. These were designated as filamentous dense bodies (FDB). In addition, the cells showed few degenerated mitochondria, occasional rough endoplasmic reticulum (RER), myelin figures, and variable numbers of pinocytotic vesicles. Lysosomes varied in size and number. They were limited by single membranes and contained an electron dense matrix. Some of them had iron particles within them. Smooth endoplasmic reticulum (SER), golgi apparatus and ribosomes were lacking in this type. These cells had several features resembling myogenic cells.

2. Another type of cell commonly encountered had a cell membrane with identical features to the cell described above. The extensive microvilli and the cell membrane were seen as membrane-bound spaces within the periphery of the cell. Pinocytotic vesicles were abundant. Moderate number of cytoplasmic organelles were identified (Fig. 3). These were mitochondria of varying sizes, myelin figures, few RER profiles, lysosomes and ribosomes. A number of mitochondria revealed crystalline inclusions (Fig. 3) within them. Few to moderate numbers of microfilaments were also present within these cells. No lipid droplets, basement membranes or tight junctions were seen. These cells exhibited no tendency to form or line vascular channels. In the absence of these features these cells were not typical of endothelial cells al-
though they possessed some of their features.

3. The third cell type not infrequently present had several features of a fibroblast. These were elongated cells with large ovoid nuclei. The cytoplasm showed prominent RER profiles and free ribosomes. Golgi complexes were also identified. Mitochondria were few to moderate in number and few pinocytotic vesicles were also present. Microfilaments were seen around the nucleus and beneath the cell membrane. No collagen was iden-
Fig. 5. A close up of 3 myxoma cells. Cytoplasmic organelles are moderate in number. Mitochondria, free ribosomes, microfilaments (arrow) and golgi apparatus (arrow head) are also identified. Cell junctions are ill defined. Nuclei are elongated and ovoid. ×12,600

tified in proximity to these cells (Figs. 4, 5).

Many cells had features of both smooth muscle cells and fibroblast and were thus labelled as myofibroblasts. In addition, macrophages, some of which contained hemosiderin, and a few lymphocytes and plasma cells were also identified.

**DISCUSSION**

A difference of opinion has always existed regarding the histogenesis of cardiac myxomas. Several histochemical and electron microscopic studies have shown conclusively that these are true neoplasms. On the other hand, a group of workers have postulated that myxomas arise from mural thrombi.

Several types of variably differentiated cells, such as macrophages, endothelial, fibroblast-like and smooth muscle cells were encountered in the present study. Most of these cells contained numerous thick and thin filaments. Cytoplasmic filaments have now been described in a large number of normal and abnormal mesenchymal cells, thus making it difficult to differentiate the various types of cells.

In the first electron microscopic study, Zuidema et al observed sparse numbers of elongated primitive-appearing, mesenchyme-like cells embedded in an abundant matrix. In addition to the usual cytoplasmic organelles, the tumour cells contained numerous membrane-limited droplets resembling secretion droplets. The latter was not observed in any of the 4 cases under
study. Similar to the present study, Matsuyama and Ooneda\textsuperscript{5)} observed cells having cytoplasmic filaments of unspecified diameters, numerous tubules of RER, ovoid dense areas, interdigitations and collagen and elastic fibres in the stroma. They also observed hematopoietic foci in haemorrhagic areas, and a few cross striated tadpole shaped tumour cells that resembled those seen in embryonal botryoid rhabdomyosarcoma. In contrast to this, we did not observe any hematopoietic foci and cross striated fibres. Silverberg and Kay\textsuperscript{14)} and Fine\textsuperscript{17)} observed in a fine granular stroma polyhedral cells that contained abundant RER, secretory vacuoles and moderate numbers of small mitochondria. Neither of them described cytoplasmic filaments. Fine\textsuperscript{17)} concluded that myxomas are slow growing tumours that arise from mesenchymal cells, while Silverberg and Kay\textsuperscript{14)} pointed out that they are endothelial in origin.

Merkow et al\textsuperscript{6)} observed similar electron microscopic features as reported by us and others.\textsuperscript{3, 4, 6, 8, 9, 10, 11} They considered the cytoplasmic filaments as being in the same size range as those of smooth muscle cells, and believed, therefore, that myxoma cells should be classified as a myoid type of endocardial (endothelial) or subendothelial cell. In a recurrent left atrial myxoma, Kelly and Bhagwat\textsuperscript{7)} found a single cell type, which they considered endothelial in character. These cells had prominent nucleoli, basement membranes, centrioles, and peculiar intralysosomal crystalloids in addition to features similar to those described in other cardiac myxomas. They regarded this tumor as having been derived from endocardial reserve cells.

It appears from our study as well as several others,\textsuperscript{3, 4, 6, 8, 9, 10, 11, 17, 18} that myxomas contain several types of mesenchymal cells in varying stages of differentiation which resemble muscle cells, fibroblasts, endothelial cells and cells having features of both smooth muscle and fibroblasts (myofibroblasts). Ultrastructural examination of the normal endocardium shows the presence of several of the mesenchymal cells outlined above.\textsuperscript{21)} A prominent feature of the cells constituting the myxomas was the presence of microfilaments within the cytoplasm. Filaments, however, have been described in a large variety of normal as well as tumour cells.\textsuperscript{18)} These filaments possibly form a cytoskeleton that provides structural support to the cells. Immunofluorescence studies using antibodies against smooth muscle myosin and actomyosin have shown the presence of these proteins in the atrial endocardium and capillary endothelium.\textsuperscript{22)}

Myxomas occur in otherwise normal hearts and are invariably located on the left side of the atrial septum. Experimentally,\textsuperscript{23)} thrombi when implanted in the heart undergo a progressive reduction in size until they are completely organized. Myxomas in tissue culture have distinct morphologic
differences from thrombi. Biochemical analyses have shown that myxomas contain chondroitin 4 and/or 6 sulphates predominantly and that dermatan sulphate is absent. The latter is present in thrombi and this observation suggests that myxomas are neoplasms rather than thrombi.

The presence of mesenchymal cells in intermediate stages of differentiation as seen ultrastructurally suggests that myxomas may represent a neoplasm, hyperplasia or a hamartoma. The observations by several authors and by us have demonstrated cells resembling smooth muscle cells, fibroblasts, endothelial cells etc. There were, however, very few well differentiated mesenchymal cells. Thus hamartoma is an unlikely possibility since by definition it consists of an accumulation of mature cells normally present at that site. Stein et al reviewed some lesions that showed electron microscopic evidence of proliferation of subendothelial reverse cells in response to varied intrinsic and/or extrinsic stimuli. Smooth muscle cell proliferation is well documented in experimental as well as human atherosclerosis. Ultrastructural studies of thickened endocardium in cases of tetralogy of Fallot and thickened aortic cusps also revealed abundant proliferation of subendothelial mesenchymal cells.

Whether cardiac myxoma represents an unusual form of hyperplasia or a true neoplasm, it appears that this unique lesion arises from multipotential mesenchymal cells located in the subendocardium which, after proliferation, are capable of differentiating into various types of connective tissue cells.
