Diagnostic Value of Integrated Ultrasonic Backscatter in Congestive Cardiomyopathy

Kemal Baysal, M.D.,* Serap Uysal, M.D.,** and Arman Bilgin, M.D.***

SUMMARY

Congestive cardiomyopathy is a fatal myocardial disease which can be diagnosed by clinical findings, electrocardiography, roentgenography and echocardiography. Tissue characterization and pathology have been determined recently using histogram methods to analyze ultrasonographs. In this study ultrasonic backscatter analysis for differentiation of normal and diseased myocardium was tested. Two-dimensional echo data and radio frequency signals of long-axis views of the left ventricular posterior wall of 10 healthy children and 14 patients with congestive cardiomyopathy in systolic and diastolic phase were digitized online into the computer memory. Cyclic variation was obtained in the control group but no variation was detectable in myopathic hearts.

Key Words:
Integrated ultrasonic backscatter Congestive cardiomyopathy

Congestive cardiomyopathy is characterized by massive cardiomegaly as a result of the extensive dilatation of the ventricles, especially of the left one. Myocardial performance is poor as evidenced by reduced stroke volume, low ejection fraction and increased systolic and diastolic volumes.¹⁻³ Many attempts have been made to differentiate tissue characteristics of cardiomyopathic myocardium from that of normal myocardium with ultrasound. Ultrasonic attenuation and backscatter, which have been quantified for the purpose of myocardial tissue characterization, reflect acoustic properties of the tissues.²¹,³¹ In this study, patients diagnosed as having congestive cardiomyopathy were studied using an M-mode format integrated backscatter imaging system to characterize the range of cyclic variation of integrated backscatter, and were compared with normal subjects.

SUBJECTS AND METHODS

A total of 14 patients and 10 healthy children were included in this study. Eight males of 6 months to 4 years of age and 6 females of 1 year to 6 years of age with congestive cardiomyopathy and an age matched control group of 6 males and 4 females were analysed. The etiology of the cardiomyopathy was idiopathic in our patients. General characteristics of the patients are shown in Table I. Two-dimensional M-mode ultrasonography integrated backscatter images were obtained in both the patients and healthy children. M-mode two-dimensional echocardiographic studies were performed using ultrasonography (Toshiba Sonolayer SSA-90A, Tokyo) with a 3.75 MHz transducer. A certain area on the left ventricle posterior wall was designated.

For each subject a one square cm area on the left ventricular posterior wall was measured in pixels and measurements of the ultrasonograph were made accordingly by the computer. The histogram indicated the gradation characteristics of the area specified on an image obtained by the ultrasound diagnostic system in quantitative form. Histogram display:

1. Horizontal axis: Gradation (64 grades, 0–63).

The maximum frequency was normalized on the display and regarded as the maximum display (100 pixels) on the vertical axis (Fig. 1). Calculations were determined by the analyser in the machine according to the formulas seen in Table II.

Statistical analysis was carried out using Student's t-test.

RESULTS

The left ventricular posterior wall histogram values of the patients with congestive cardiomyopathy were $36.3\pm4.5\%$ for systole and $36.2\pm4.1\%$ for diastole. No statistically significant difference between these two values was found in the group. Systolic $(33.1\pm6.8\%)$ and diastolic $(26.1\pm10\%)$ values obtained in the control group were statistically different. In Table III, the histogram results of the groups are displayed.

DISCUSSION

Clinical echocardiography, which is often employed at present, enables the evaluation of M-mode patterns and two-dimensional images of the smooth, large interfaces of the heart such as endocardial and epicardial surfaces. Quantitative evaluation of echoes of lower amplitude, such as those from the myocardium has widely been used clinically. It may be useful in the diagno-
ysis of myocardial structure and perfusion and may be accomplished by the analysis of radio frequency data to determine integrated ultrasonic backscatter occurring in response to cardiac contraction on echo image data which would be important to show the abnormalities in myocardial structure.\(^5\),\(^6\) Integrated ultrasonic backscatter from normal myocardium has been shown to vary with the phase of cardiac contraction (decreasing from end-diastole to end-systole).\(^3\)\(^\text{--}^5\) We analysed 24 subjects (14 patients, 10 controls) with echocardiographic imaging, and integrated backscatter was measured with the two-dimensional imaging system. The histogram values at the end of systole and diastole were calculated; a significant difference between these two values was not found in the patients with congestive cardiomyopathy.

Two studies of histogram values in congestive cardiomyopathy were found in the literature.\(^7\),\(^8\) In a series of 20 cases, left ventricular posterior wall histogram values for systole and diastole were different, but no statistical difference was found.\(^7\) In the other study, whereas a healthy control group showed cyclic variations, there was no cyclic variation in the patients with congestive cardiomyopathy.\(^8\) We obtained entirely different results in our patients in comparison with the second study.\(^8\)

We demonstrated the disappearance of the difference caused by the decreased transmission of radio frequency waves through the altered myocardium. In conclusion, in cardiomyopathic patients the cyclic variation of the left ventricle histogram values disappear. Therefore, left ventricular posterior wall histogram values may be useful for the diagnosis of myocardial change in congestive cardiomyopathy.
