Low Incidence of Hemorrhagic Infarction Following Coronary Reperfusion with Nasaruplase in a Canine Model of Acute Myocardial Infarction

Comparison with Recombinant t-PA

Hideaki Kido, Ph.D., Kazutaka Hayashi, M.S., Takeshi Uchida, Ph.D. and Masahiro Watanabe, Ph.D.

SUMMARY

An examination was made of the coronary thrombolytic effects of nasaruplase in a canine model of acute myocardial infarction. The model was produced by selective injection of an artificial thrombus into the coronary artery stenosed by laser ablation. Intravenous nasaruplase (8 U/kg/min) showed an equivalent thrombolytic effect to a recombinant tissue-type plasminogen activator (rt-PA, 10,000 IU/kg/min) as assessed by reperfusion rate (78.6 versus 79.2%) and reperfusion time (37.4 ± 5.2 versus 37.0 ± 2.5 min). Nasaruplase decreased the plasma α₂-plasmin inhibitor (α₂-PI) level by 28% immediately after reperfusion, but hardly altered fibrinogen or plasmin-α₂-plasmin inhibitor complex (PIC) levels. By contrast, rt-PA significantly decreased plasma α₂-PI and fibrinogen levels, by 84% and 92% respectively, and, increased PIC level more than 70-fold. Hemorrhagic infarction occurred in 2 of 14 animals in the nasaruplase group and in 9 of 19 animals in the rt-PA group. In these animals, significant correlations were found between the ratio of the hemorrhagic infarction area to total infarct area and the plasma α₂-PI ($r = -0.740, p < 0.05$) or fibrinogen ($r = -0.798, p < 0.05$) concentrations, as well as between the recovery rate of left ventricular regional wall motion and the plasma α₂-PI ($r = 0.924, p < 0.01$) or fibrinogen ($r = 0.864, p < 0.01$) concentrations. It is concluded that nasaruplase is a potent thrombolytic agent which preserves left ventricular function with a lesser rate of hemorrhagic infarction than rt-PA. Further, nasaruplase administration results in recovery of left ventricular regional wall motion and systolic function, such as Vmax. (Jpn Heart J 35: 61–79, 1995)

Key words: nasaruplase scu-PA myocardial infarction animal model thrombolysis systemic fibrinogenolysis hemorrhagic infarction left ventricular function t-PA reocclusion
ISSUE-TYPE plasminogen activator (t-PA) is widely used for thrombolytic therapy in acute myocardial infarction (AMI). Although t-PA shortens thrombolysis time and raises the reperfusion rate compared with either urokinase (UK) or streptokinase (SK), bleeding complications remain a risk of t-PA therapy. Although hemorrhagic infarction has generally been considered a reperfusion injury, the incidence of hemorrhagic infarction has been found to be increased by thrombolytic agents, occurring in about half of patients receiving such agents. Hemorrhagic infarction is observed within the reperfused area of the ischemic myocardium. However, there exists the opposite opinion that hemorrhagic infarction may enlarge the infarct size beyond the reperfused area. In fact, the mass of hemorrhagic infarction varies and the factors determining hemorrhagic infarct size remain obscure.

Nasaruplase is a native single-chain UK-type plasminogen activator (scu-PA) derived from a human kidney cell line. It is a proenzyme converted only at the thrombus surface. Nasaruplase has higher selectivity than UK for fibrin lysis. Intracoronary administration of nasaruplase in humans has been shown to recanalize the occluded coronary arteries in 90% of patients while showing weaker systemic fibrinogenolytic effects than UK. In the present study, we compared the thrombolytic effects and incidence of hemorrhagic infarction and its relation to left ventricular function and infarct size after intravenous administration of nasaruplase to t-PA in a canine model of AMI.

**MATERIALS AND METHODS**

**Animals:** Adult mongrel dogs of both sexes (KEARI, Japan) weighing 8 to 19 kg were anesthetised by intravenous injection of 30 mg/kg of sodium pentobarbital, intubated and ventilated with room air at a rate of 20 respirations/min with a 20 ml/kg stroke volume.

**Thrombolytic agents:** Nasaruplase (400U/mg) was highly purified from the culture medium of a human kidney cell line (Green Cross Corp., Japan). t-PA was a recombinant product (Activasin®, 600,000 IU/ml, Kyowa Hakko Kogyo Co., Japan). Each agent, dissolved in physiological saline, was prepared immediately before use.

**Animal model of acute myocardial infarction:** A guiding catheter (9F, Medtronic) was inserted into the ostium of the left coronary artery through the right carotid artery of the dog under fluoroscopic guidance. After coronary artery angiography (CAG) and left ventriculography (LVG) to define the baseline state, a 1.7 mm hot-tip YAG laser probe (MYL-3, Olympus, Japan) was inserted into the middle segment of the left anterior descending coronary artery (LAD) and the artery ablated at 14 W for 2 sec to produce a 50 to 90% stenosis.
The artificial thrombus was made by mixing arterial blood (2 ml), fibrinogen (20 mg, Green Cross Corp.) and thrombin (30 units, Green Cross Corp.). The thrombus (2 x 2 x 8 mm in size) was then injected into the stenosed portion of the LAD to initiate AMI. Thirty minutes later, nasaruplase (8 U/kg/min) or rt-PA (10,000 IU/kg/min), each dose corresponding to about 1.5 times that used in the respective clinical studies, was administered intravenously after a bolus injection of 2500 IU heparin. Reperfusion was defined as successful when recanalization was verified by CAG or when a reperfusion arrhythmia occurred within 60 min. When reperfusion was attained, the thrombolytic agent was stopped. Animals which developed ventricular fibrillation due to reperfusion arrhythmias were defibrillated. Defibrillation induced bradycardia in some animals, but the heart rate recovered rapidly. The catheters were then removed and the surgical incision in the neck was sutured. Antibiotics (penicillin and kanamycin) were injected intramuscularly. All dogs were cared for according to institutional guidelines.

The dogs were again anesthetized 1 week later, and a 9F guiding catheter was inserted into the left carotid artery. Coronary reocclusion was assessed by CAG, and LVG was performed to measure left ventricular function. Thrombolytic therapy was not performed in the control group.

**Determination of plasma concentrations of fibrinogen, α2-plasmin inhibitor (α2-PI), plasmin-α2-plasmin inhibitor complex (PIC) and thrombin anti-thrombin III complex (TAT):** Blood samples were taken from the carotid artery prior to coronary artery occlusion, at 30 min after occlusion, immediately after reperfusion and after a week recovery period. Plasma was obtained immediately from 9 ml of whole blood to which 1 ml of 3.2% trisodium citrate was added. All plasma samples were kept frozen for later analysis. Commercially available kits were used for the measurement of fibrinogen (International Reagent Co., Japan), α2-PI (Daiichi Chemical Co., Japan), PIC (Teijin, Japan) and TAT (Teijin).

**Electrocardiogram and hemodynamic measurements:** Lead II electrocardiograms (ECG) were monitored throughout the experiment. Systemic arterial blood pressure (BP) was measured with a pressure transducer (Statham P-50, Gould). The heart rate (HR) was analyzed with a tachometer (Nihon Kohden, Japan). A catheter-tip pressure transducer (MPC-500, Millar Instruments) was inserted into the left ventricle through the right femoral artery to measure left ventricular end-diastolic pressure (LVEDP), LV dP/dt, LV dP/dt/P, V_max and time constant (T). Cardiac output (CO), pulmonary arterial blood pressure (PAP) and pulmonary capillary wedge pressure (PCWP) were measured using a 5F Swan-Ganz catheter (TC-504, Viggo-Spectramed). Stroke volume (SV), systemic vascular resistance (SVR), total pulmonary vascular resistance (TPR) and pulmo-
nary vascular resistance (PVR) were calculated from standard formulae. Parameters were recorded continuously with a polygraph system (RM-6000, Nihon Kohden).

**Measurements of left ventricular function:** The left ventricular ejection fraction (LVEF) and regional wall motion (rWM) were calculated from 30° right anterior oblique ventriculograms with a computer analysis system (CAD-98, Nishimoto Industry, Japan) using Dodge’s method\(^{17}\) and the radial-area method,\(^{18}\) respectively.

**Quantification of infarct size:** The animals were sacrificed with a lethal dose of pentobarbital sodium one week after infarction. The hearts were excised, weighed, cut cross-sectionally into plates 8 mm thick and stained with 0.5% 2,3,5-triphenyltetrazolium chloride solution (TTC). The infarct size was identified as the non-TTC-stained area. Relative cardiac (heart/body) weight was also calculated as an indicator of cardiac hypertrophy induced by myocardial infarction. Hemorrhagic infarction was quantified gross anatomically and histologically, and the hemorrhagic infarction ratio was calculated as:

\[
\text{hemorrhagic infarction ratio (\%) = } \frac{\text{area of hemorrhagic infarction}}{\text{total infarct area}} \times 100
\]

**Statistical analysis:** Results are expressed as mean ± SEM. The frequency of hemorrhagic infarction or reocclusion was statistically analysed with a \(\chi^2\) test. The survival rate was analysed using the Kaplan-Meier method. Values between two groups were analysed using the two-tailed nonpaired \(t\) test. Other parameters were analysed applying Tukey’s method for multiple comparisons. The results were considered significantly different if \(p < 0.05\).

**RESULTS**

**Thrombolytic effect:** Representative photographs of the results of thrombolytic therapy are shown in Figure 1. During 30 min following coronary artery occlusion, the thrombus expanded on the upstream side of the LAD (Figure 1-C). When nasaruplase was administered intravenously after 30 min of coronary artery occlusion, coronary recanalization was achieved in 78.6% (11/14) of animals within 20 to 55 min after the start of infusion (Figure 1-D). rt-PA induced successful thrombolysis in 79.2% (19/24) of animals within 20 to 50 min after the start of infusion. The average time to reperfusion was 37.4 ± 5.2 min in the nasaruplase group and 37.0 ± 2.5 min in the rt-PA group (Table I). Spontaneous recanalization occurred in none of the control animals during a 1 week observation period.

In the nasaruplase group, coronary recanalization was achieved in 11 of 14 animals. Three of the 11 animals died within 1 week. Coronary reocclusion was observed in 1 of the 8 survivors at 1 week. In the rt-PA group, coronary recanalization was achieved in 19 of 24 animals. Since 5 of the 19 animals developed cardiac arrest immediately after reperfusion, they were excluded from the study. Four of the 14 remaining animals died within 1 week. Reocclusion was observed in 3 of the 10 survivors at 1 week. Moreover, 1 of the 7 non-reoccluded animals had a high-grade restenosis at the laser ablation site and one animal had circulatory insufficiency at the apex in the rt-PA group.
Changes in plasma concentrations of \( \alpha_2\)-PI, fibrinogen, PIC and TAT:
There were no significant differences between the three groups regarding plasma concentrations of \( \alpha_2\)-PI, fibrinogen, PIC or TAT before coronary artery occlusion (Table II). TAT was significantly increased 30 min after occlusion, but \( \alpha_2\)-PI, fibrinogen and PIC showed little change at this stage. Administration of nasaruplase significantly decreased \( \alpha_2\)-PI (−28% vs before occlusion) but displayed little effect on fibrinogen, PIC or TAT immediately after reperfusion. In contrast, rt-PA dramatically decreased \( \alpha_2\)-PI (−84%) and fibrinogen (−92%) and increased PIC (more than 70-fold). The plasma concentrations of \( \alpha_2\)-PI, fibrinogen and PIC were significantly different between the two thrombolytic agents immediately after reperfusion. All parameters returned to pre-occlusion levels at 1 week post infarction (Figure 2).

Survival and reocclusion rates: In the nasaruplase group, 3 of 11 animals died within 1 week. Coronary reocclusion was observed in 1 of the 8 survivors (12.5%) at 1 week. Since 5 of the 19 animals in the rt-PA group developed
Figure 3. Time course of survival rates in a canine model of AMI. —: nasaruplase \( (n=10) \), --: rt-PA \( (n=11) \), -----: control \( (n=14) \). Reoccluded animals were excluded from the analysis.

cardiac arrest immediately after reperfusion, they were excluded from the study. Four of the 14 remaining animals died within 1 week. Reocclusion was observed in 3 of the 10 survivors (30%) at 1 week. Moreover, in the rt-PA group, 1 of the 7 remaining animals had a high-grade restenosis at the laser ablation site and another animal had circulatory insufficiency at the apex (Table I). Seven of 14 animals died within 1 week in the control group. The survival rates in the nasaruplase, rt-PA and control group, excluding reoccluded animals, were 70% (7/10), 62.5% (7/11) and 50% (7/14), respectively (Figure 3).

Electrocardiogram: ST-segment and T-wave elevations were observed immediately after coronary artery occlusion in this canine model of AMI. Treatment with nasaruplase and rt-PA reduced these elevations immediately after reperfusion. Reperfusion arrhythmias were observed infrequently for the next 5 to 10 min. Premature ventricular contractions, atrioventricular block, ventricular tachycardia and ventricular fibrillation then gradually appeared. After 1 week, the T-wave was elevated slightly in a few animals from both thrombolytic agent groups. Abnormal Q-waves were observed in 2 of the 7 animals of the control group.

Hemodynamics: There were no statistically significant differences in hemodynamics between the three groups before coronary artery occlusion (Table II). There was no significant change in BP or HR. The CO and SV decreased gradually in the control group as a result of sustained coronary occlusion. No early recovery of CO and SV immediately after reperfusion with either nasaruplase or rt-PA was observed; however, CO and SV returned to pre-occlu-

NS: not significant

Serum levels after 1 week, especially in the nasaruplase group. The SVR and LVEDP rose during AMI and recovered 1 week after thrombolytic therapy. There was a significant difference in LVEDP between the nasaruplase group and the control group at 1 week. The mean PAP, PCWP, TPR and PVR gradually rose in the control group for 1 week. These parameters recovered to baseline at 1 week in each thrombolytic agent-treated group.

**Left ventricular function:**

*Left ventriculographic investigation:* The LVEF was lowered significantly by AMI and did not recover in the control group 1 week later. Left ventricular function in the nasaruplase group was improved 1 week after reperfusion, but not immediately after reperfusion. The effect of rt-PA was weaker than that of nasaruplase (Figure 4).

Regional wall motion (rWM) in segments 1, 2 and 3, corresponding to the left ventricular anterobasal, anterolateral and apical portions, respectively, was reduced significantly by AMI, compared to baseline. The rWM in segment 3 improved after 1 week, but segment 2 was unchanged in the control group. A significant improvement of rWM in segments 1 and 2 was observed in the nasaruplase group 1 week after reperfusion. There was only slight improvement...
Figure 4. Changes in left ventricular ejection fraction. $\square$ = nasaruplase ($n=7$), $\blacksquare$ = rt-PA ($n=7$), $\square$ = control ($n=7$). A: Before coronary artery occlusion, B: 30 min after thrombus injection, C: Immediately after reperfusion, D: 1 week later. Vertical bars represent SEM *: $p<0.05$, **: $p<0.01$ vs A, ++: $p<0.01$ vs B, #: $p<0.05$

of rWM in the rt-PA group (Figure 5). In segments 4 (diaphragmatic) and 5 (posterobasal) corresponding to non-infarct area, rWM also showed the tendency to decrease following the occlusion of LAD, but the degree was slight and not significant.

Hemodynamic investigation: $V_{max}$, which indicates left ventricular systolic function, decreased following AMI. A further fall was observed at 1 week in the control group. Nasaruplase slightly improved these parameters immediately after reperfusion and they improved significantly at 1 week post infarction compared to 30 min after coronary occlusion and to the parameters in the control group. The improvement of LV function after rt-PA, compared with that produced by nasaruplase, was slight (Figure 6).

A T prolongation was observed after AMI, which indicates deterioration of left ventricular diastolic function. Nasaruplase and rt-PA did not improve LV diastolic function immediately after reperfusion. There were no differences in this parameter between the three groups at 1 week (Figure 6).

Anatomic findings: In the control group widespread transmural necrosis was commonly observed at 1 week, between the left ventricular anterolateral portion and the apex, representing the area perfused by the occluded vessel. The necrotic myocardium was denatured and fibrotic. Necrosis in the nasaruplase and rt-PA groups was generally localized to the internal area of the left ventricle. Hemorrhagic infarction was observed in 2 of the 14 animals in the nasaruplase and control group (including dead animals), at up to 1 week. By contrast, the frequency of hemorrhagic infarction in the rt-PA group (9/19) was significantly

higher than in the other two groups (Figure 7, Table III).

**Infarct size and relative cardiac weight:** Infarct sizes were 4.6 \( \pm \) 2.7, 5.2 \( \pm \) 2.5 and 25.7 \( \pm \) 6.2% in the nasaruplase, rt-PA and control groups, respectively.
Nasaruplase and rt-PA reduced infarct size to an equal degree (Figure 8). The relative cardiac weights were 0.70 ± 0.04, 0.85 ± 0.05 and 0.97 ± 0.09% in the nasaruplase, rt-PA and control groups, respectively. Nasaruplase significantly suppressed cardiac hypertrophy subsequent to AMI as assessed by relative cardiac weight. The effect in the rt-PA group was not significantly different from the control group (Figure 9).

**Correlation between hemorrhagic infarction and other parameters:** A sig-

EFFECT OF NASARUPLASE IN AN AMI MODEL

Figure 10. Decrease in plasma concentrations of α2-PI and fibrinogen in animals with hemorrhagic infarction.

Plasma concentrations of α2-PI and fibrinogen immediately after reperfusion were decreased significantly, compared with those in non-hemorrhagic infarction animals.

● = nasaruplase; ▲ = rt-PA

Figure 11. Delay of recovery in left ventricular function in animals with hemorrhagic infarction.

Recovery of left ventricular regional wall motion of the anterolateral portion and LV systolic function (Vmax) 1 week after reperfusion was statistically inferior to that in non-hemorrhagic infarction animals.

● = nasaruplase; ▲ = rt-PA

A significant decrease in plasma α2-PI and fibrinogen concentration occurred immediately after reperfusion in the animals which had hemorrhagic infarction (Figure 10). Moreover, the recovery of left ventricular regional wall motion at the anterolateral portion (Seg. 2) and Vmax after 1 week was inferior in animals with hemorrhagic infarction (Figure 11). Correlation coefficients between the hemorrhagic infarction ratio and the plasma α2-PI and fibrinogen concentrations immediately after reperfusion were −0.740 (p < 0.05; α2-PI) and −0.798 (p < 0.05;
fibrinogen) (Figure 12). Correlations between these hemostatic changes and the recovery of regional wall motion after 1 week were 0.924 (p < 0.01; $\alpha_2$-PI) or 0.864 (p < 0.01; fibrinogen) (Figure 13).

**DISCUSSION**

The usefulness of intravenous thrombolytic therapy in the treatment of AMI has motivated the development of new agents having a high affinity for thrombi. Animal models similar to human AMI are indispensable in the development of new drugs. Through intracoronary laser ablation, the present animal
model provides examples not only of damage to the endothelium but also stenosis of the coronary artery, which are both important factors in the incidence of thrombosis. The stenosis is still observed after 1 week, indicating that it is not the result of temporal vasospasm. AMI is induced by selectively inserting a fibrin-rich artificial thrombus into the stenosed portion of the coronary artery under closed-chest conditions. Since electrocardiographic observation revealed a transient elevation of ST-segments and T-waves after coronary occlusion that was lowered during subsequent coronary recanalization and reperfusion arrhythmias, the responses in this model resemble AMI in humans. Spontaneous reperfusion did not occur in the control group for up to 1 week. This model was thus considered suitable for the investigation of both acute and chronic effects of thrombolytic agents.

The reperfusion rate of nasaruplase in this model was 78.6%, which is the same as results for both a clinical study (75.0%) and for recombinant scu-PA (saruplase). Moreover, no difference in reperfusion rates was observed between nasaruplase and rt-PA (79.2%) in the present study. It has been reported that the thrombolytic potency of scu-PA is almost equivalent to that of rt-PA in studies in other animal models. Nevertheless, the significant decreases in plasma α2-PI and fibrinogen, and the marked increase in PIC were observed only in the rt-PA-treated group immediately after reperfusion. This is due to the fact that nasaruplase is the inactive proenzyme of UK, whereas t-PA itself is active. Accordingly, α2-PI concentration was gradually decreased by the addition of rt-PA, but not of nasaruplase, to human plasma in vitro. This result suggests that the systemic fibrinolytic action of rt-PA is more potent than that of scu-PA.

It has been suggested that bleeding complications are related to the degree of systemic fibrinolysis. Systemic hemorrhage has often been observed during treatment with rt-PA. On the other hand, the bleeding complications of scu-PA are benign when compared with those related to rt-PA or streptokinase, suggesting that scu-PA is a safe thrombolytic agent.

The frequency of hemorrhagic infarction in the nasaruplase group was significantly lower than in the rt-PA group. The infarct size in the two thrombolytic agent groups was equal, and hemorrhagic infarction did not enlarge the infarct size beyond the reperfused area. However, the ratio of the area of hemorrhagic infarction to total infarct area (hemorrhagic infarction ratio) was higher in the rt-PA group than in the nasaruplase group. In general, the size of hemorrhagic infarction is dependent on reperfusion time, which was the same in the two thrombolytic agent groups. In the animals with hemorrhagic infarction, a significant negative correlation was found between the hemorrhagic infarction ratio and plasma α2-PI and fibrinogen concentrations immediately after reperfusion. From these results, hemorrhagic infarction might be expected to
extend within the reperfused area, especially in cases with accelerated systemic fibrinogenolysis at the time of reperfusion.

LVEF and rWM at anterobasal, anterolateral and apical portions worsened as a result of the decrease in cardiac function, including non-infarct areas. These changes reflected both the acute coronary occlusion and the enlargement of infarct area following growth of the thrombus. These parameters recovered the pre-occlusion level after 1 week in the nasaruplase group. The recovery in the rt-PA group was poor compared to that in the nasaruplase group. In hemorrhagic infarction animals, rWM was inferior to that in non-hemorrhagic animals. Moreover, a significant positive correlation was found between the recovery of left ventricular function at the area of infarction and systemic fibrinogenolysis. Hemorrhagic infarction delays the recovery of left ventricular function, due to microcirculatory damage or an increase in the perfusion pressure of the myocardial tissue. The difference between nasaruplase and rt-PA was apparent in Vmax, which is an index of cardiac function at systole. It is thus suggested that massive hemorrhagic infarction may have some effect on left ventricular systolic function.

Increased load on the left ventricle following coronary artery occlusion induces ventricular remodeling and reactive hypertrophy in the residual myocardium. Nasaruplase suppressed the development of hypertrophy, as a result of early reduction in ventricular loading. rt-PA was less effective than nasaruplase but more effective than the control. Thus, it is suggested that hemorrhagic infarction delays left ventricular remodeling.

All hemostatic parameters returned almost to baseline in all groups after 1 week. There were, however, differences in coronary reocclusion rates between the nasaruplase (12.5%) and the rt-PA (30%) groups. Perfusion insufficiency of coronary blood flow in the rt-PA group rose to 50%, including high-grade restenosis and circulatory impediment at the apex. In clinical studies, reocclusion rates of rt-PA have been reported to be 5 to 20% (early phase) up to 24 hours after reperfusion and 30% (late phase), which is higher than after streptokinase therapy. In addition, mutant t-PA, which has a longer half-life in blood than rt-PA, has shown higher reocclusion rates than rt-PA. It has been suggested that t-PA has direct or indirect procoagulant effects, such as a rebound increase in plasma coagulation factors. In contrast, scu-PA showed a low incidence of both early (1–1.5%) and late (2.7–5.0%) reocclusion. These data suggest that scu-PAs are superior to t-PAs for preventing coronary reocclusion.

**ACKNOWLEDGEMENTS**

The authors would like to thank Dr. Y. Uchida and Dr. C. Heldebrant for critical
comments on the manuscript. The authors also thank Y. Kubo, S. Inoue and Y. Narita for expert technical assistance.
