Paramolar Tubercle, Deciduous Dentition, Extra cusp

Abstract
Many variations in crown morphology are seen. The most common among these are accessory cusps present on the crown surface. These accessory cusps most commonly occur on the molars (cusp of Carabelli), incisors (Talon’s cusp) and premolars (Leong’s premolar). To date, the dental literature has reported very few cases with a morphological variation on the mesio-buccal cusp of the deciduous molars. We herein present 2 cases where we observed an extra cusp on the buccal surface of the deciduous maxillary first molar adjacent to the mesio-buccal cusp. A groove separates this cusp from the mesio-buccal cusp. This cusp was present bilaterally in one case and unilaterally in the other. Presence of this anomaly may necessitate modification of treatment plans and treatment procedures in children.

Introduction
There are various types of dental morphological anomalies, with anomalies of the crown being more common than those of the root. Such anomalies may be found in the form of an extra cusp or tubercle. In 1916, Bolk was the first to describe the formation of an additional cusp on the buccal surfaces of the upper and lower permanent molars (1). In 1925, Leigh reported an enamel tubercle on the maxillary right third molar of an Eskimo skull (2). Extra cusps have subsequently been described by many authors (3, 4, 5), with forms varying on premolars, molars and incisors. Paramolar tubercle is a term used for an accessory cusp or tubercle located on the buccal surface of premolars and molars (6). The cases presented in this paper highlight the presence of such tubercles on deciduous molars.

Embryologically, these cusps/tubercles are thought to develop from an abnormal proliferation and folding of the inner enamel epithelium and subjacent ectomesenchymal cells of the dental papilla into the stellate reticulum of the enamel organ (7). The molecules formed by the primary enamel knot are thought to induce the initiation of secondary enamel knots at the areas of epithelial folding that mark cusp formation in the early bell stage of tooth formation. The resultant cusp morphogenesis and positions appear to form sequentially and cusps that form late in development, after the main cusps, are typically small. The secondary enamel knots disperse after formation of the cusp tips, indicating the termination of crown morphogenesis (7). The paramolar tubercle reported in the present two cases is smaller than the main cusps and may therefore have appeared later in development. The presence of these extra cusps or tubercles may be a cause for dental problems such as caries in the pits and fissures between the tubercle and buccal cusp. Knowledge of these anomalies holds evolutionary importance and also helps in treatment planning for problems associated with such anomalies.

Case Report
Case 1
A 6-year-old female patient arrived at the Department of Pediatric Dentistry with a chief complaint of decayed teeth
in the upper right back region of the jaw and bleeding from gums while brushing. There was no history of pain, and past medical and dental histories were not noteworthy. Intraoral examination revealed a fair oral hygiene status with no evidence of stains or calculus. Hard tissue examination revealed a very interesting morphological variation of the deciduous maxillary right and left first molars. A small tubercle or cusp-like projection was observed on the buccal surface of both the deciduous maxillary first molars, adjacent to and separated by a groove from the mesio-buccal cusp (Fig.1). Dental caries involving the enamel and dentin were observed in this groove in relation to both the deciduous first molars. No other anatomical structural variations were observed, apart from the cusp of Carabelli, which was seen on both of the deciduous maxillary second molars. Maxillary and mandibular impressions were made for academic interests.

Case 2

A 5-year-old male patient arrived at the department of pediatric dentistry with a chief complaint of bleeding gums for about 1 month. Past medical and dental histories were not noteworthy. Intraoral examination revealed generalized mild calculus. A small tubercle or cusp-like projection was seen on the buccal surface of the left deciduous maxillary first molar, which was similar to that observed in the previous case (Fig.2). The tubercle was adjacent to and was separated by a groove from the mesio-buccal cusp. An accessory central cusp and a cusp of Carabelli were seen on the deciduous maxillary left second molar. Maxillary and mandibular impressions were made for academic interests (Fig.3).

Discussion

Accessory cusps or tubercles of the crowns of deciduous teeth are rare. The size, shape and location of these anomalies vary widely and various names have been proposed for such anomalies in the literature. The cusps that were observed in the present cases were located on the buccal surface of the deciduous maxillary first molar and were clearly separated by a groove from the mesio-buccal cusp. A cusp-like projection of this kind seen on permanent teeth has previously been described in literature as the paramolar tubercle (1) and the authors used the same term.
for describing this structural variation on the deciduous maxillary first molars.

Various names and descriptions have been proposed for extra cusps seen on deciduous molars. Kallay (5) earlier referred to similar projections as protuberantio apulpalis or tuberculum pulpale. Although a well-formed cusp was not described, he noted that deciduous maxillary first molars may have a cone-shaped projection on the mesio-buccal side which is separated from the buccal cusp by a semilunar groove. Wolpoff has referred to large teeth with extra cusps, particularly of the deciduous maxillary first molars, as xcw(qEmolarized deciduous molars' (8). According to Butler, deciduous first molars are interesting from an evolutionary point of view because of the various degrees of molarization that they show (9). The term ‘protostylid’ has been used by Dahlberg for a tubercle or an extra cusp found on the buccal side of mesio-buccal cusp of mandibular molars, both deciduous and permanent (10). However, this term is not used for the maxillary molars. Schulge has described five types of morphological variation on the posterior teeth (11) (Table1). The literature reports very few cases of paramolar tubercle on premolars and molars (12, 13), and the authors have not found another case report of a paramolar tubercle on the deciduous maxillary first molar.

**Conclusion**

Variations in dental morphology have drawn interest among researchers in terms of evolutionary and genetic studies. This paper highlights two cases with a paramolar tubercle on the deciduous maxillary first molar. It is of interest to note whether a similar variation will appear in the permanent successor or counterpart. The involvement of certain genes in the formation of these cusps in the deciduous and permanent dentition is of particular interest. The cases presented in this paper were followed in order to evaluate whether the permanent dentition would show evidence of similar morphological variations.
