(Received January 29, 1990 and in revised form March 26, 1990)

Abstract: A cross-sectional study was performed on 165 male lead-exposed workers to clarify the quantitative relationships between less severe exposure to lead and its effects on renal function in 1985. Mean and range of blood lead concentration (Pb-B) were 36.5 µg/dl and 6-73 µg/dl, respectively. Duration of lead exposure was 0.1 to 26.3 years. No lead-related changes were detected in serum creatinine concentration, beta-2 microglobulin in urine, creatinine clearance, beta-2 microglobulin clearance, and uric acid clearance. Twenty of the 165 workers had been exposed to lead for more than 10 years with mean duration of 21.0 years. Average concentrations of Pb-B in each individual during 1972 to 1984 were 26.1-66.6 µg/dl. Renal function indices of these 20 workers were not different from those of remaining lead-exposed workers whose lead exposure duration were 10 years or less. These results suggest that long-term less severe exposure to lead up to 70 µg/dl of Pb-B may not cause adverse effects on renal glomerular function and proximal tubular function.

Key words: Lead—Long-term exposure—Renal function—Cross-sectional study—Dose-effect relationship

The kidney is known to be one of the target organs in both acute and chronic lead poisoning. Acute massive exposure to lead induced renal proximal tubular dysfunction with Fanconi syndrome1,2) and lead-containing intranuclear inclusion bodies in the proximal tubule cells.1,3-6) Prolonged heavy exposure to lead caused progressive chronic nephropathy resulting in chronic renal failure and contracted kidney.7-12) Excess death from chronic renal disorders has also been reported in some worker population with long-term lead exposure.13,14)

However, the dose-effect relationship with regard to renal effect has remained unclear and controversial for long-term less severe exposure to lead15). The
purpose of this cross-sectional study in 1985 was to clarify the quantitative relationships between long-term less severe exposure to lead and its effects on renal function.

**SUBJECTS AND METHODS**

The number of lead-exposed workers surveyed was 192. All of them were male working in a lead storage battery manufacturing factory and had no past or present history of renal disease, diabetes mellitus or essential hypertension with or without administration of anti-hypertensive drugs.

Renal function was assessed by measuring serum creatinine concentration (Cr-S), creatinine clearance (Cr-C), beta-2 microglobulin in urine ($\beta_2$MG-U), beta-2 microglobulin clearance ($\beta_2$MG-C), and uric acid clearance (UA-C).

Urine and venous blood were collected at the working place. All subjects were asked to drink 500 ml of water and to urinate about 20 to 30 min later. About one hour later after the first urination, they were called again and urine and venous blood were collected for clearance study and determination of Pb-B, with the greatest caution taken against lead contamination of samples. The renal clearance values were adjusted to the standard body surface area of 1.73 m².

Whole blood was pretreated by the method of Stoeppler and Brandt, and Pb-B was measured by flameless atomic absorption spectrometry (Z-7000, Hitachi) under the internal quality control using pooled blood and control blood specimens (Control Blood for Metals 1, BEHRING INSTITUT). Serum and urinary beta-2 microglobulin were determined by enzyme immunoassay (Imzyne $\beta_2$-M, FUJIREBIO).

Twenty-seven of the 192 subjects were excluded from statistical analysis because urinary flow rate between the first and second urination was 1 ml/min or less, even though 500 ml water load method was strictly adhered to. Thus, number of lead-exposed workers analyzed was 165. Age of the 165 workers was 18.4–57.3 years and exposure length to lead was 0.1–26.3 years.

Thirty-one of the 165 workers have been exposed to lead for more than 10 years. Determination of Pb-B was carried out since 1972 by Hessel's method. However, because measurements of Pb-B had been one of the secondary screening items until recent year, Pb-B of 11 of the 31 long-term lead-exposed workers were measured only 3 times or less during the followed period. Thus, it was not appropriate to assess their past Pb-B levels from available Pb-B data and they were eliminated from the analysis of long-term lead effects on the renal function. Pb-B of the 20 long-term lead-exposed workers analyzed been measured 5 to 20 times during 1972 to 1984. Exposure duration to lead was 10.2 to 26.3 years with mean of 21.0 years, and age was 28.4 to 50.5 years, with mean of 41.7 years.
RESULTS

Information from industrial physicians and nurses indicated that renal dysfunction probably due to excess exposure to lead have not been seen at least for the last decade, and all hypertensive employees eliminated from the study did not show any signs of renal dysfunction from data of periodical health examinations performed at the interval of 6 months.

Concentrations of Cr-S and Pb-B in 27 workers eliminated from statistical analysis because of small amount of urinary flow rate were not different from the 165 workers analyzed.

: p<0.05, 0.01 between the two groups. GM: Geometric mean.
Pb-B of the 165 workers was 6 to 73 μg/dl with mean of 36.5 μg/dl. Table 1 shows renal function indices categorized by Pb-B levels. Significant differences between the categorized groups were found sporadically but dose-effect relationships were not clear.

Table 2 shows partial correlation coefficients between Pb-B and renal clearance indices keeping age, urinary flow rate, serum concentration of the pertinent substances constant and, in cases of β₂MG-C and UA-C, glomerular filtration rate (GFR, Cr-C was substituted.) constant. No informative correlation was observed.

Figure 1 illustrates the chronological changes of Pb-B of the 20 long-term lead-exposed workers. Average concentration of Pb-B calculated from available data during 1972 to 1984 in each individual was 26.1 to 66.6 μg/dl, and maximal concentration in each individual ranged from 34 to 87 μg/dl, respectively. Pb-B in 1985 were not exceptional in comparison with past levels.

Table 3 shows mean and range of age, exposure length to lead, Pb-B, and
LEAD EXPOSURE AND RENAL FUNCTION

renal function indices in the 20 long-term lead-exposed workers and short-term lead-exposed workers whose exposure length was less than 10 years. Age was significantly older and Pb-B was significantly higher in the 20 long-term lead-exposed workers, but the renal function indices were not different between the two groups.

To adjust the effects of aging, urinary volume and, in cases of $\beta_2$MG-C and UA-C, GFR, prediction equations for the renal function indices were calculated from the data of the 134 short-term lead-exposed workers by linear multiple regression procedure, and %-predicted vaues of the renal function indices in the 20 long-term lead-exposed workers were assessed. Table 4 shows the %-predicted values of the renal clearance indices. No differences were found between two groups.

Means of the %-predicted values of renal clearance indices in the 11 long-term lead-exposed workers eliminated from the analysis were 99.05% (sd=1.93) in Cr-C, 99.97% (sd=12.38) in UA-C, and 101.14% (sd=17.43) in $\beta_2$MG-C. These values were not different from those in the 20 long-term lead-exposed workers analyzed.

DISCUSSION

At most working sites of the factories surveyed, current environmental lead levels were below 0.1 mg/m³, the recommended occupational exposure limit by the Japan Association of Industrial Health, but in some areas they exceeded the recommended limit resulting in the rather wide range of Pb-B. Though exact past environmental levels of lead could not be determined, the past and present Pb-B levels in the 20 long-term lead-exposed subjects suggested that they should have been similar to the present ones.

Neither Cr-S nor Cr-C showed any noticeable relationships with Pb-B in the cross-sectional observation. Results of Cr-S and Cr-C of the long-term lead-exposed workers also indicated that renal glomerular function was not affected by long-term less severe exposure to lead.

Some authors reported the effects of lead on renal function in low- or middle-level exposure to lead. Hammond et al. found that serum urea nitrogen in secondary lead smelter workers was correlated with lead exposure indices with
Pb-B of 25 to 101 \( \mu g/dl \). Yamamura et al.\(^{20}\) reported that blood urea nitrogen (BUN) was increased in 4 of 15 male lead-exposed Shippoh-yaki (Japanese cloisonne) workers whose Pb-B was 70 to 147 \( \mu g/dl \), but serum creatinine concentrations were within the normal range. Hong et al.\(^{21}\) stated that routine clinical tests such as BUN and Cr-S were not sufficiently sensitive to detect the early effects of lead but that GFR was decreased in lead-exposed workers with 34 to 110 \( \mu g/dl \) Pb-B. On the other hand, Buched et al.\(^{22}\) reported that Cr-C in 25 lead-exposed workers whose Pb-B were 62 \( \mu g/100 \text{ml} \) or below was normal, Pocuck et al.\(^{23}\) found that Pb-B did not have any relation with Cr-S and Greenberg et al.\(^{24}\) reported that Cr-C in 38 workers whose Pb-B ranged from 9 to 60 \( \mu g/dl \) was not correlated with Pb-B.

The lack of increased \( \beta_2 \text{MG-U} \), \( \beta_2 \text{MG-C} \) indicates that renal reabsorbtional function for these glomerular filtrable substances at the level proximal tubular cells was not affected by lead. Buchet et al.\(^{22}\) reported that \( \beta_2 \text{MG-U} \) and \( \beta_2 \text{MG-C} \) in 25 workers with Pb-B of 62 \( \mu g/100 \text{ml} \) or below were normal. Vacca et al.\(^{25}\) concluded that tubular proteinuria including beta-2 microglobulinuria was not an early manifestation of toxicity of lead exposure from data of 7 lead-exposed workers whose Pb-B ranged from 83.5 to 390 \( \mu g/dl \) and who had been exposed to lead for at least 5 years. Greenberg et al.\(^{24}\) suggested that there was no direct relationship between low levels of lead exposure and urate metabolism. On the other hand, Hong et al.\(^{21}\) suggested that decrease of tubular reabsorptive capacity for glucose was related to lead exposure.

In conclusion, adverse effects on function of glomerular filtration and tubular reabsorption of microglobulin and urate may not be induced by lead exposure when the level of Pb-B is controlled up to 70 \( \mu g/dl \).
