Abducens Nerve Palsy and Ipsilateral Incomplete Horner Syndrome: A Significant Sign of Locating the Lesion in the Posterior Cavernous Sinus

Teruyuki Kurihara

Key words: abducens nerve palsy, Horner syndrome, posterior cavernous sinus, sympathetic nerve fibers

DOI: 10.2169/internalmedicine.45.0163

It is a rare combination of neurological manifestations to have abducens nerve palsy and ipsilateral incomplete Horner syndrome. When a patient has right abducens nerve palsy he will complain of double vision and the image becomes more doubled when he looks to the right since his right eye cannot abduct. In addition he has right postganglionic Horner syndrome which causes mild right ptosis, and his right pupil is smaller than the left pupil. He does not have any sweating abnormality of his right face, since his Horner syndrome is postganglionic. Complete Horner syndrome includes anhidrosis of the face (1). Incomplete Horner syndrome includes ptosis, miosis without anhidrosis.

The abducens nerve is the 6th cranial nerve traveling from the pons to the lateral rectus muscle of the eye following a long and tortuous course passing over the hard temporal bone and this cranial nerve is vulnerable to trauma, pressure, inflammation, ischemia, diabetes mellitus (diabetic ophthalmoplegia). This nerve shows paresis as a false localizing sign in increased intracranial pressure.

Horner syndrome can occur in any one of the interruptions when the sympathetic nerve travels ① from the hypothalamus descending through the ipsilateral sympathetic pathways in the brain stem to the spinal cord, ② from the spinal cord to the superior cervical ganglion (preganglionic fiber), and ③ from the ganglion to the orbit (postganglionic fiber) accompanying the internal carotid artery (1, 2). Common localizations of the lesion (2) causing Horner syndrome include the lateral hypothalamic area (complication after thalamotomy for dyskinesia), the lateral medulla (Wallenberg syndrome), the spinal cord (syringomyelia), the lung apex (Pancoast tumor), brachial plexus palsy (Klumpke’s palsy), the neck (traumatic wound, cervical adenopathy), carotid artery (thrombosis), cavernous sinus (carotid aneurysm, carotid-cavernous fistula, tumor, trauma, inflammation), the orbit (retroorbital tumor), the ciliary ganglion (destructive lesion), and even cluster headache (2) can cause Horner syndrome.

Tsuda et al. (3) originally presented a case of abducens nerve palsy and Horner syndrome due to metastatic parotid carcinoma to the cavernous sinus in 2005, and the authors accumulated 9 cases with helps of neuro-ophthalmologists and reported them in 2006 (4). The ages of 9 patients ranged from 28 to 63 years, 6 male and 3 female cases. Five patients with extracavernous sinus lesions had headache, and four patients with intracavernous sinus lesions did not have a headache. Their Horner syndrome included mild ptosis and miosis without anhidrosis. After appropriate treatment, abducens nerve palsy improved in 5 out of 9 cases, but Horner syndrome persisted in all 9 cases. The complete Horner syndrome includes ptosis, miosis, and ipsilateral anhidrosis of the face; these symptoms occur in the case of preganglionic sympathetic injury. The sympathetic nerve fibers governing facial sweating travel along the external carotid artery after leaving the superior cervical ganglion (5). That is the reason why postganglionic injury does not cause anhidrosis.

The etiology of abducens nerve palsy and Horner syndrome includes metastatic tumor (from parotid carcinoma, stomach cancer, small cell carcinoma of the lung, breast cancer), epipharynx carcinoma, meningioma, extension of chordoma, intracavernous internal carotid artery aneurysm, carotid-cavernous fistula, head trauma, cryptococcal meningitis, herpes zoster ophthalmicus, sphenoidal sinus cyst).

Neither abducens nerve palsy, nor Horner syndrome promptly indicates the location of the lesion; however, when both are present it is of significant value to determine the site of the lesion. If we review the anatomical course of the ocular sympathetic nerve, postganglionic sympathetic fibers travel over the wall of the internal carotid artery and then ascend to the brain and in the cavernous portion the sympathetic fibers leave the internal carotid artery and accompany...
the abducens nerve for only a few millimeters in the poste-
rior portion of the cavernous sinus, and then leave the ab-
ducens nerve to join the first division of the trigeminal
nerve (5).

The combination of abducens nerve palsy and ipsilateral
postganglionic Horner syndrome has been reported since
1981 by Abad et al (6, 7) and there are 19 cases in the En-
gle language literature (6, 8-14). Another 8 cases were
added by Tsuda et al in 2006 (4), since one of the nine
cases had been already reported in 2005 (3). Although the
present clinical manifestations are rare, abducens nerve
palsy and ipsilateral Horner syndrome has a significant
value to localize the neurological lesion since abducens
nerve and sympathetic fibers meet for only a few millime-
ters in the posterior portion of the cavernous sinus. The pho-
tograph in the article of Tsuda et al clearly shows the pre-
cise neuroanatomy of this narrow area (3, 4).
